In the Norfolk Infirmary, the mortality has been much less in children than adults. But at St. Bartholomew's, the proportion of death in children during the 20 years that I frequently attended operations for stone there was very great. In the Bristol Infirmary, the risk in children seems to have been about equal to what it has been in adults. In all calculations of this kind, however, it is to be recollected, that as operations for the stone are done not only by surgeons of various degrees of skill, but in different ways, and even with instruments of great diversity, such computations do not give the fair average of any one method of operating.

Now, where the patients are equally favourable, but the results of any given number of operations on them are considerably different, the skill of the surgeons, the particular methods of operating pursued, the kinds of instruments used, the general healthiness of the hospital itself, and the treatment after the patients are put to bed, are considerations by which questions apparently inexplicable might sometimes be solved.

From the year 1772 to 1816, the Norwich Hospital received 18,859 patients of all kinds, making an average of 428 annual admissions; and Dr. Marcet observes, that the proportion of 506 operations of lithotomy out of 18,859 patients, which corresponds to about 1 in 38, exceeds in an astonishing degree that obtained from any of the other public institutions, whose records he examined.

Next to the records of the Norwich Hospital, Dr. Marcet derived the most distinct information of this

kind from Cheselden, who mentions in his work on anatomy, that during the course of his public practice in St. Thomas's Hospital, a period of about 20 years, he had performed the operation of the stone 213 times, and lost only 20 patients. This was about 2 cases in 21, which is much less than the common average.

In St. Thomas's Hospital, during ten years, the operation of lithotomy had been done on an average 11 times in each two years; and one case of stone had occurred in each 528 patients admitted.

In St. Bartholomew's, lithotomy was performed 56 times in the years 1812, 1813, 1814, 1815, and 1816. The annual average about 11, or 1 in each 340 patients of all descriptions.

In Guy's Hospital, lithotomy had been performed on an average about 9 or 10 times annually, during the space of 20 or 30 years. The proportion of calculous patients there was also estimated by Dr. Marcet as 1 in about 300 cases of all kinds.

Dr. Marcet's inquiries inclined him to think that, on the whole, lithotomy in the London hospitals for some years has been gradually becoming less frequent; and this, he conceives, may be owing partly to a real reduction in the frequency of the stone, from some alteration in the diet or habits of the people; partly to the use of appropriate medicines; and partly to the circumstance of calculous patients not resorting so exclusively as was formerly the case to the great London hospitals for the operation.

In the Royal Infirmary at Edinburgh, the average number of stone cases annually, during the six years preceding the period of Dr. Marcet's publication, is said not to have exceeded 2, although about 2000 patients had been admitted there every year.

Dr. Marcet was informed by M. Roux, that in La Charité at Paris, ten or twelve cases of stone occur every year out of about 2600 patients, and that the proportion of deaths from the operation there is 1 in 5 or 6.

With respect to the Hôpital des Enfans Malades, in the same city, Dr. Marcet states, on the authority of Dr. Biett, that about 6 cases of stone are received every year into that establishment, where about 3000 children of both sexes are annually admitted. There have been only 3 cases in females, and, what is remarkable, only 2 deaths from the operation in the course of the last seven years.

Dr. Marcet has been acquainted that lithotomy is comparatively rare at Vienna; not on account of the want of good surgeons, or the unfrequent occurrence of stone cases in that part of the continent, but in consequence of the little attention paid to this disease by the most eminent surgeons of the Austrian capital.

At Geneva, says Dr. Marcet, in a population of 30,000, lithotomy has been performed only thirteen times in the last twenty years, though good surgeons are never wanting in that town to perform the operation whenever an opportunity presents itself. Out of these thirteen patients, seven were not strictly Genevese, though belonging to the neighbouring districts, and one was an Englishman; so that the disease would, at first sight, appear to be a rare occurrence at Geneva. But, continues Dr. Marcet, *if the smallness of the Genevese population be taken into account*, this proportion of calculous cases may not fall very short of that observed in other places. At Lyons, a populous town not more than eighty miles distant from Geneva, the disease is stated to be rather frequent.

With regard to the chemical nature of urinary calculi, there was nothing known until 1776, when Scheele published on the subject in the Stockholm Transactions. He there stated, that all the urinary calculi which he had examined consisted of a peculiar concrete substance, now well known by the name of *lithic* or *uric* acid, which he also showed was soluble in alkaline lixivia. Scheele farther discovered that the lithic matter was in some degree capable of being dissolved in cold water; that this solution possessed acid properties, and in particular that of reddening litmus; that it was acted upon in a peculiar manner when boiled in nitric acid; and, lastly, that human urine always contained this substance in greater or less quantity, and often let it separate in the form of a brick-coloured sediment by the mere effect of cooling.

The discovery made by Scheele was confirmed by Bergmann and Morveau, and the investigation of the subject was afterward prosecuted by others with redoubled ardour. As Professor Murray observes, experiments continued to be repeated and diversified on these concretions and on their solvents. At length, it was fully ascertained that there existed others, besides those composed of uric acid; and latterly, our knowledge of them has been much extended by the researches of Pearson, Wollaston, Fourcroy, and Vauquelin. Several important facts have also been established by the talents and industry of some other distinguished men, viz. Dr. Henry, of Manchester; Professor Brande, of the Royal Institution of London; Dr. Marcet, late of Guy's Hospital; and Dr. Prout, of London. The facts and considerations of the latter writer render it probable, however, that the common opinion of pure lithic acid being contained in the urine is not exactly correct; but that this acid "in healthy urine exists in a state of combination with ammonia, and that in reality this fluid contains no uncombined acid at all."—(*On the Nature, &c. of Gravel and Calculus, c.* 13.)

The credit which is due to Dr. Wollaston for his valuable and original discoveries respecting urinary calculi is very considerable; a truth, which I have particular pleasure in recording here, since his merits have not been fairly appreciated by the French chemists. Indeed, as Dr. Marcet observes, it is the more desirable that his claims should be placed in the clearest point of view, as the late celebrated M. Fourcroy, both in his "Système des Connoissances Chimiques," and in his various papers on this particular subject, has in a most unaccountable manner overlooked Dr. Wollaston's labours, and, in describing results exactly similar to those previously obtained and published by the English chemist, has claimed them as his own discoveries. Yet Dr. Wollaston's paper was printed in our Philosophical Transactions two years before Fourcroy published his Memoir in the "Annales de Chimie," and three years before he gave to the world his "Système des Connoissances Chimiques;" and he discussed in these works a paper of Dr. Pearson on the lithic acid, published in a volume of the Philosophical Transactions (for 1798) subsequent to that which contained the account of Dr. Wollaston's discoveries!—(See *Marcet's Essay on Calculous Disorders, p.* 60. Also *Murray's Syst. of Chem. vol.* 4, *p.* 636, *edit. of* 1809.)

It would appear, then, that Scheele first discovered the nature of those urinary calculi which consist of lithic acid, but that Dr. Wollaston first ascertained the nature of several other kinds, some of which have also been described at a later period by Fourcroy and Vauquelin. On the whole, there are five species of concretions, whose chemical properties were first pointed out by Dr. Wollaston, and no less than four belong to the urinary organs. These are, 1st, Gouty concretions. 2dly, The fusible calculus. 3dly, The mulberry calculus. 4thly, The calculus of the prostate gland. 5thly, The cystic oxide, discovered in 1810.

1. *Lithic Acid Calculus.* Dr. Prout believes, that at least two-thirds of the whole number of calculi originate from lithic acid; for, as it forms by far the most common nucleus, round which other calculous matter is subsequently deposited, if such nuclei had not been formed and detained, two persons at least out of three who suffer from stone, would never have been troubled with the disorder.—(*On Gravel, Calculus, &c p.* 95.)

Lithic acid forms a hard, inodorous concretion, of a yellowish or brown colour, similar to that of wood of various shades. According to Professor Murray calculi of this kind are in fine, close layers, fibrous or radiated, and generally smooth on their surface, though sometimes a little rough. They are rather brittle, and have a specific gravity varying from 1.276 to 1.786, but usually about 1.500. One part of lithic acid is said to dissolve in 1720 parts of cold water, and 1150 parts of boiling water (*Marcet, p.* 65); and this solution turns vegetable blues to a red colour. When it has been dissolved in boiling water, small yellowish crystals are deposited as the fluid becomes cold. Lithic acid calculi blacken, but are not melted by the blow-pipe, emitting a peculiar animal smell, and gradually evaporating, until a small quantity of white ash remains, which is alkaline. By distillation, they yield ammonia and prussic acid. They are soluble, in the cold, in a solution of pure potassa or soda, and from the solution a precipitate of a fine white powder is thrown down by the acid

Lime-water likewise dissolves them, but more sparingly. According to Scheele, they remain unchanged in solutions of the alkaline carbonates; a statement which agrees with that of Dr. Prout, who accounts for the effect said to be produced by the alkaline carbonates upon calculi in the bladder by their property of dissolving the lithate of ammonia.—(*Egan, in Trans. of Irish Acad.* 1805. *Prout, On Gravel, &c. p.* 84.) They are not much acted upon by ammonia. They are not soluble either in the muriatic or sulphuric acid; though they are so in the nitric when assisted by heat, and the residue of this solution, when evaporated to dryness, assumes a remarkably bright pink colour, which disappears on adding either an acid or an alkali. In many of these calculi, the lithic acid is nearly pure; in others there is an intermixture of other ingredients, particularly of phosphate of lime, and phosphate of ammonia and magnesia; and in almost all of them, there is a portion of animal matter which occasions the smell when they are burnt, and the loss in their analysis.—(See *Murray's Chemistry, vol.* 4, *p.* 640; and *Marcet's Essay on the Chem. and Med. Hist. of Calculous Disorders*, 8*vo. Lond.* 1817.)

A great quantity of uric acid is formed in gouty constitutions, and deposited in the joints or soft parts in the state of lithate of ammonia. Sir Everard Home removed a tumour weighing four ounces from the heel of a gentleman, a martyr to the gout; and when analyzed by Professor Brande, it was found to be principally composed of uric acid.—(*On Strictures, vol.* 3, *p.* 313.)

2. *Lithate of Ammonia Calculus*, according to Dr. Prout, is generally of the colour of clay. Its surface is sometimes smooth; sometimes tuberculated. It is composed of concentric layers, and its fracture resembles that of compact limestone. It is generally of small size, and rather uncommon; but the lithate of ammonia very frequently occurs, mixed with lithic acid, forming a mixed variety of calculus. Under the flame of the blow-pipe, it usually decrepitates strongly. It is much more soluble in water than the lithic acid calculus; and always gives off a strong smell of ammonia on being heated with caustic potash. *The lithate of ammonia is also readily soluble in the alkaline subcarbonates, which pure lithic acid is not.*—(*Prout, On Gravel, &c. p.* 83.)

3. *Bone Earth, Phosphate of Lime Calculus.* The presence of phosphate of lime in urinary calculi had been mentioned by Bergmann and others, when Dr. Wollaston first ascertained that some calculi are entirely composed of it. From the investigations of Dr. Wollaston, it appears that this substance sometimes, though rarely, composes the entire calculus, but that in general it is mixed with other ingredients, particularly with uric acid and phosphate of magnesia and ammonia. In the first case, the calculus is described as being of a pale-brown colour, and so smooth as to appear polished. When sawed through it is found very regularly laminated, and the laminæ, in general, adhere so slightly to each other, as to separate with ease into concentric crusts. It dissolves entirely, though slowly, in muriatic or nitric acid. Exposed to the flame of the blow-pipe, it is at first slightly charred, but soon becomes perfectly white, retaining its form, until urged with the utmost heat from a common blow-pipe, when it may be completely fused. It appears to be more fusible than the phosphate of lime, which forms the basis of bone; a circumstance which Dr. Wollaston ascribes to the latter containing a larger quantity of lime.—(*Phil. Trans.* 1797.)

4. *Triple Phosphate of Magnesia and Ammonia Calculus.* The existence of this calculus in the intestines of animals was first pointed out by Fourcroy; but its being a constituent part of some urinary calculi of the human subject was originally discovered by Dr. Wollaston.—(*Phil. Trans.* 1797.) According to Dr. Prout, this species of calculus is always nearly white: its surface is commonly uneven, and covered with minute shining crystals. Its texture is not laminated, and it is easily broken and reduced to powder. In some rare instances, however, it is hard and compact, and when broken, exhibits a crystalline texture, and is more or less transparent. Calculi composed entirely of the phosphate of magnesia and ammonia are rare, but specimens in which they constitute the predominant ingredient are by no means uncommon.—(*Prout, p.* 86.) When the blow-pipe is applied, an ammoniacal smell is perceived, the fragment diminishes in size, and if the heat be strongly urged, it ultimately undergoes an imperfect fusion, being reduced to the state of phosphate of magnesia.—(*P.* 69.) Dr. Wollaston describes the form of the crystals of this salt as being a short trilateral prism, having one angle a right angle, and the other two equal, terminated by a pyramid of three or six sides. These crystals, as Dr. Marcet has explained are but very sparingly soluble in water, but very readily in most, if not all the acids, and on precipitation, they reassume the crystalline form. From the solutions of these crystals in muriatic acid, sal ammoniac may be obtained by sublimation. Solutions of caustic alkalies disengage ammonia from the triple salt, the alkali combining with a portion of the phosphoric acid. One fact, of great importance, respecting this species of calculus is mentioned by Sir A. Cooper in his lectures; viz. that it is particularly liable to be reproduced after lithotomy, and therefore, until the patient's diathesis has been corrected by medical treatment, he cautions surgeons not to perform the operation. In cases of this description, he says, a substance like mortar is discharged from the bladder, and the urine is very fetid.

5. *Fusible Calculus.* Mr. Tennant first discovered that this substance was different from the lithic acid, and that, when urged by the blow-pipe, instead of being nearly consumed, a large part of it melted into a white vitreous globule. The nature of the fusible calculus was afterward more fully investigated and explained by Dr. Wollaston.—(*Phil. Trans.* 1797.) According to the excellent description lately given of this calculus by Dr. Marcet, it is commonly whiter and more friable than any other species. It sometimes resembles a mass of chalk, leaving a white dust on the fingers, and separates easily into layers, or laminæ, the interstices of which are often studded with sparkling crystals of the triple phosphate. At other times, it appears in the form of a spongy and very friable whitish mass, in which the laminated structure is not obvious. Calculi of this kind often acquire a very large size, and they are apt to mould themselves in the contracted cavity of the bladder, assuming a peculiarity of form which Dr. Marcet has never observed in any of the other species of calculi, and which consists in the stone terminating, at its broader end, in a kind or peduncle, corresponding to the neck of the bladder. The chemical composition of the fusible calculus is a mixture of the triple phosphate of magnesia and ammonia, and of the phosphate of lime. These two salts, which, when separate, are infusible, or nearly so, when mixed together and urged by the blow-pipe, easily run into a vitreous globule. The composition of this substance, says Dr. Marcet, may be shown in various ways. Thus, if it be pulverized, and acetic acid poured upon it, the triple crystals will be readily dissolved, while the phosphate of lime will scarcely be acted upon; after which the muriatic acid will readily dissolve the latter phosphate, leaving a small residue, consisting of lithic acid, a portion of which is always found mixed with the fusible calculus.

It is also remarked by Dr. Marcet, that many of the calculi which form round extraneous bodies in the bladder are of the fusible kind. And the calculous matter sometimes deposited between the prepuce and glans is found to be of the same nature.

6. *Mulberry Calculus*, or *Oxalate of Lime*, is mostly of a dark-brown colour, its interior being often gray. Its surface is usually uneven, presenting tubercles more or less prominent, frequently rounded, sometimes pointed, and either rough or polished. It is very hard, difficult to saw, and appears to consist of successive unequal layers: excepting the few stones which contain a proportion of silica, it is the heaviest of the urinary concretions. Though this calculus has been named *mulberry*, from its resemblance to that fruit, yet as Dr. Marcet has observed, there are many concretions of this class, which, far from having the mulberry appearance, are remarkably smooth and pale-coloured, as may be seen in plate 8, fig. 6, of that gentleman's essay. According to Mr. Brande, persons who have voided this species of calculus, are much less liable to to a return of the complaint, than other patients who discharge lithic calculi.—(*Phil. Trans.* 1808.)

With regard to chemical characters (says Professor Murray), it is less affected by the application of the usual reagents than any other calculus. The pure alkaline solutions have no effect upon it, and the acids dissolve it with great difficulty. When it is reduced,

however, to fine powder, both muriatic and nitric acid dissolve it slowly. The solutions of the alkaline carbonates decompose it, as Fourcroy and Vauquelin have observed; and this affords us the easiest method of analyzing it. The calculus in powder being digested in the solution, carbonate of lime is soon formed, which remains insoluble, and is easily distinguished by the effervescence produced by the addition of weak acetic acid, while there is obtained in solution the compound of oxalic acid with the alkali of the alkaline carbonate. From this the oxalic acid may be precipitated by the acetate of lead or of barytes; and this oxalate, thus formed, may be afterward decomposed by sulphuric acid. Another method of analyzing this calculus is by exposure to heat: its acid is decomposed, and by raising the heat sufficiently, pure lime is obtained, amounting to about a third of the weight of the calculus. According to Fourcroy and Vauquelin, the oxalate of lime calculus contains more animal matter than any other. This animal matter appeared to them to be a mixture of albumen and urée. The composition of a calculus of this species, analyzed by Mr. Brande, was oxalate of lime, 65 grains; uric acid, 16 grains; phosphate of lime, 15 grains; animal matter, 4 grains.

7. *The Cystic Oxide Calculus* is small, and very rare. It was first described by Dr. Wollaston.—(*Phil. Trans. for* 1810.) In external appearance, it bears a greater resemblance to the triple phosphate of magnesia than any other sort of calculus. However, it is more compact, and does not consist of distinct laminæ, but appears as one mass confusedly crystallized throughout its substance. It has a yellowish semi-transparency, and a peculiar glistening lustre. Under the blow-pipe, it gives a singularly fetid smell, quite different from that of lithic acid, or the smell of prussic acid. In consequence of the readiness with which this species of calculus unites both with acids and alkalies, in common with other oxides, and the fact of its also containing oxygen (as is proved by the formation of carbonic acid by distillation), Dr. Wollaston named it an oxide, and the term *cystic* was added from its having been originally found only in the bladder in two examples. Dr. Marcet, however, has subsequently met with no less than three instances of calculi formed of cystic oxide, all of which were unquestionably of *renal* origin.

8. *Alternating Calculus.* Lithic strata frequently alternate with layers of oxalate of lime or with the phosphates. Sometimes also the mulberry alternates with the phosphates, and in a few instances, three or even four species of calculi occur in the same stone, disposed in distinct concentric laminæ. On the comparative frequency of these and other varieties of calculi, Dr. Prout's work contains valuable information.

9. *Compound Calculi, with their Ingredients intimately mixed.* Under this title, Dr. Marcet comprehends certain calculi which have no characteristic feature by which they can be considered as distinctly belonging to any of the other classes. He observes, that they may sometimes be recognised by their more or less irregular figure, and their less determinate colour; by their being less distinctly, if at all divisible into strata; and by their often possessing a considerable hardness. By chemical analysis, confused results are obtained.—(See *Essay on the Chem. and Med. Hist. of Calculous Disorders*, *p.* 90.)

10. *Calculi of the Prostate Gland.* The composition of these calculi is said to have been first explained by Dr. Wollaston.—(See *Phil. Trans. for* 1797.) They all consist of phosphate of lime, the earth not being redundant as in bones. Their size varies from that of a pin's head to that of a hazel-nut. Their form is more or less spheroidal; and they are of a yellowish-brown colour.

Fourcroy has described a species of urinary calculus, which is characterized by being composed of the urate or lithate of ammonia. Dr. Wollaston, Mr. Brande, and Dr. Marcet did not, however, satisfactorily ascertain the presence of this substance in any of the concretions which they examined. As also urea and the triple phosphate, both of which afford ammonia, are frequently present in lithic calculi, it is conjectured that these circumstances may have given rise to the analytical results, from which the existence of urate of ammonia has been inferred.—(*Brande, in Phil. Trans.* 1808. *Marcet's Essay*, *p.* 93.)

The recent investigations of Dr. Prout, however, tend to establish the reality of the lithate of ammonia calculus.

Dr. Marcet met with two specimens of urinary calculi, entirely different from any which have hitherto been noticed. One of these he proposes to name *xanthic oxide*, from ξανθὸς, *yellow*, because one of its most characteristic properties is that of forming a lemon-coloured compound, when acted upon by nitric acid. The chemical properties of the other new calculus, mentioned by Dr. Marcet, correspond to those of fibrine, and he therefore suggests the propriety of distinguishing it by the term *fibrinous*. For a particular description of these new substances, I must refer to this gentleman's Essay.

11. *Carbonate of Lime Calculus.* This substance is not enumerated by Dr. Marcet, as entering in the composition of urinary calculi. But according to Mr. R. Smith, there can be no doubt of the fact. Dr. W. H. Gilby, of Clifton, he says, detected it decidedly in four instances. "A notice of it will be found in Mr. Tilloch's Journ. for 1817, vol. 49, p. 188, in the account of a curious calculus, given to me by Mr. G. M. Burroughs, of Clifton; the nucleus of which is a common cinder, an inch and a half long, and one broad. Since the publication of that paper (continues Mr. Smith), Mr. H. Sully, of Wiveliscombe, sent me three oddly-shaped calculi, which he removed from a lad, together with 15 pea-sized ones previously voided by the urethra, which are entirely carbonate of lime, held together by animal mucus."—(See *Med. Chir Trans. vol.* 11, *p.* 14.) Dr. Prout has also seen some small calculi, composed almost entirely of carbonate of lime.—(*On Gravel, &c. p.* 89.)

Dr. Prout has investigated, with considerable talent, the comparative prevalency of the different forms of urinary deposites, and the order of their succession. His data are taken from the examinations made by Professor Brande, of the calculi in the Hunterian Collection; by Dr. Marcet, of those at Norwich and Guy's Hospital; by Dr. Henry, of those at Manchester; and by Mr. Smith, of others preserved at the Bristol Infirmary. The whole number of calculi examined was 823: of these, 294 were classed under the name of lithic acid, 98 of which were nearly pure; 151 were mixed with a little of the oxalate of lime; and 45 with a little of the phosphates. 113 consisted of oxalate of lime. Three were of cystic oxide; 202 were phosphates; of which 16 were nearly pure; 84 mixed with a small proportion of lithic acid; 8 consisted of phosphate of lime nearly pure; 3 of triple phosphate nearly pure; and 91 of the fusible or mixed calculi. 186 were alternating calculi, or those whose laminæ varied, but consisted of lithic acid, oxalate of lime, and phosphates: of these, 15 consisted of lithic acid and oxalate of lime, the first being in the greatest proportion; 40 of the oxalate of lime in the greatest proportion, and lithic acid in the least; 51 of the lithic acid and the phosphates; 49 of the oxalate of lime, and the phosphates; 12 of the oxalate of lime, lithic acid, and the phosphates; 1 of fusible and lithic; 2 of fusible and oxalate of lime; and 16, the composition of which was not mentioned.

Of compound calculi whose compositions was not specified, there were 25.—(See *W. Prout's Inquiry into the Nature, &c. of Gravel and Calculus*, *p.* 94.)

The proportion of *lithic acid calculi* is somewhat more than one-third of the whole number. But as this acid is the common nucleus, round which other calculous matter is deposited, Dr. Prout computes the proportion of calculi originating from it, to be at least two-thirds of the whole number. According to the experiments of the same physician, the red crystalline calculus is composed of nearly pure lithic acid; and the earthy, amorphous one consists of lithic acid, more or less ammonia, generally a little of the phosphates, and sometimes a small portion of the oxalate of lime. The lighter the colour, the greater in general the proportion of lithate of ammonia and the phosphates.—(*P.* 97.)

Oxalate of lime calculi form one-seventh of the whole number, without any regularity, however, in different museums.

Cystic oxide calculi are so rare, that the proportion found was only one in 274.

Calculi composed of the phosphates made about one-fourth of the whole number.

Alternating calculi amounted to between one-fourth and one-fifth; but Dr. Prout offers good reasons for believing that the data, from which the estimate is drawn, cannot be depended upon. For additional information on this branch of the subject, I must refer to Dr. Prout's valuable work.

The stone being a severe affliction, and the operation extremely hazardous and painful, a variety of experiments have been instituted for the purpose of discovering a solvent for urinary calculi. Hitherto, however, all the remedies and plans which have been tried, have been attended with very limited, and by no means unequivocal, success, notwithstanding many persons may have been deceived into a contrary opinion.

The dissolution of stones in the bladder has been attempted by *lithontriptic medicines*, as they are termed, and by fluids injected into this viscus. At the present day, practitioners direct their endeavours very much to the correction of those particular diatheses or states of the constitution on which the formation of various calculi depend; and more confidence seems to be placed in this aim, than in any schemes for the dissolution of urinary concretions. It is certain that, in the latter project, many difficulties present themselves; and among these, some of the most serious are, the great variety in the composition of calculi; the impossibility of knowing the exact ingredients of a stone while it is concealed in the bladder, though many useful suggestions for assisting the judgment on this point have been recently offered by Dr. Prout: and, lastly, if the right solvent were ascertained, as calculated upon chemical principles applied to urinary concretions out of the body, it is obvious, that any medicines taken by the mouth are liable to so many changes in the alimentary canal, and in the lymphatic and vascular system, that it must be exceedingly difficult to get them in an unaltered state and effective quantity into the bladder; while, if this were possible (as it is in the way of injection through a catheter), the bladder itself might be incapable of bearing the application, and the patient lose his life in the experiment.

As Dr. Prout well observes, a calculus in the bladder may be considered a substance placed in a solution of various principles in a certain quantity of water. If any of the more insoluble of these principles exist in this solution in a state of supersaturation, the calculus will afford a nucleus, round which the excess will be deposited. But if none exist in a state of excess, of course none can be deposited, and the calculus will not increase in bulk.

Whoever studies the chemical properties of the urine, says Dr. Marcet, will learn that "if any alkali (a few drops of ammonia, for instance) be added to recent urine, a white cloud appears, and a sediment, consisting of phosphate of lime, with some ammoniaco-magnesian phosphate, subsides, in the proportion of about two grains of the precipitate from four ounces of urine. Lime-water produces a precipitate of a similar kind, which is still more copious; for the lime, in combining with the excess of phosphoric, and perhaps, also, of lactic acid, not only precipitates the phosphate of lime, which these acids held in solution, but it decomposes the other phosphates, thus generating an additional quantity of the phosphate of lime, which is also deposited.

"If, on the contrary (observes the same author), a small quantity of any acid, either the phosphoric, the muriatic, or, indeed, even common vinegar, be added to recent healthy urine, and the mixture be allowed to stand for one or two days, small reddish crystalline particles of lithic acid will be gradually deposited on the inner surface of the vessel.

It is on these two general facts, that our principles of chemical treatment ultimately rest. Whenever the lithic secretion predominates, the alkalies are the appropriate remedies; and the acids, particularly the muriatic, are the agents to be resorted to, when the calcareous or magnesian salts prevail in the deposite."—(*P.* 147, 148.)

The alkalies taken into the stomach certainly reach the urinary passages through the medium of the circulation; and it is also strongly suspected that the acids likewise do so, though this circumstance is still a question. Unfortunately, the quantity of either alkalies or acids which thus mixes with the urine is so small, that no impression is made upon calculi of magnitude. The experience of Dr. Marcet, Dr. Prout, and others, however, has clearly ascertained that such medicines are often capable of checking a tendency to the formation of stone, and sometimes of bringing on a calculous deposite depending upon the altered state of the system. Indeed, Dr. Marcet expresses his decided opinion, that even supposing not an atom of alkali or acid ever reached the bladder, still it would not be unreasonable to expect that these remedies may respectively produce the desired changes during the first stages of assimilation; in one case, by neutralizing any morbid excess of acid in the primæ viæ; and in the other, by checking a tendency to alkalescence or otherwise disturbing those affinities, which, in the subsequent processes of assimilation and secretion, give rise to calculous affections.—(*P.* 153.)

When muriatic acid is prescribed, from 5 to 25 drops may be given two or three times a day, diluted with a sufficient quantity of water.

The best way of taking the alkalies is by drinking soda water as a common beverage. It is asserted, however, on the authority of Sir G. Blane that, when the alkalies are combined with citric acid, as in the ordinary saline draught, they also have the effect of depriving the urine of its acid properties.

Dr. Marcet, with every appearance of probability, refers to carbonic acid itself no solvent power; and he does not even adopt Mr. Brande's opinion, that this acid passes into the urine, when patients drink fluids impregnated with it.

But it may be inquired, if no known internal medicine will dissolve a stone already formed, what is the good of merely altering the diathesis and checking the increase of the calculus, as lithotomy must still be necessary? The reasons for persevering in the aim of correcting any particular state of the system and the urinary secretion, on which state the increase of a calculus depends, are very important; for it is found, that though medicines may be quite incapable of dissolving a calculus, they relieve a great deal of the distress and suffering apparently the effect of the diathesis itself, as will be presently noticed, and sometimes afford such ease, that the operation may be postponed until the health is improved, or, in a very old subject, even be dispensed with altogether. The aim is also of high importance, with the view of preventing relapses.

As the lithic acid diathesis seems to be concerned in the production of about two-thirds of the whole number of the urinary calculi, the correction of it has been a chief aim among modern practitioners. For this purpose, Magendie, whose experiments tend to prove, that the lithic acid diathesis may be lessened and removed by abstinence from animal food, and other nutriments abounding in azote, founds his practice very much upon this alleged fact. His indications, however, are four in number, viz. 1. To lessen the quantity of uric acid produced by the kidneys; 2. To augment the secretion of urine; a maxim which leads him to consider cutaneous perspiration injurious; a statement which I think must be rejected, considering the rarity of calculi in hot climates, independently of the sentiments of Dr. Wilson Philip, that the precipitating acid (if such be the cause) is thrown off by the skin, and consequently that ensuring a due performance of the cutaneous functions must, in these cases, be beneficial.—(See *Medical Trans. of the College of Physicians, vol.* 6.) 3. To prevent the lithic acid from assuming a solid form by saturating it. 4. When gravel and calculi are formed, to promote their discharge and attempt their dissolution.—(*Recherches, &c. sur la Gravelle, p.* 42.)

For correcting the lithic acid diathesis, Dr. Prout particularly enjoins the avoidance of errors in diet, exercise, &c. The error of quantity of food he deems worse than the error of quality. Patients, he says, should abstain altogether from things which manifestly disagree with them, and which must be unwholesome to all; such as heavy unfermented bread, hard boiled and fat puddings, salted and dried meats, acescent fruits, and (if the digestive organs be debilitated) soups of every kind. In general also wine, and particularly those of an acescent quality should be avoided. The wearing of flannel, the preserving a regular state of the bowels, and the occasional use of alterative medicines are likewise commended.—(*Prout, On Gravel, &c. p.* 135.)

According to the same author, the treatment of calcu-

lous affections is either of a local or general description. The local treatment is nearly the same in all the species; the general treatment will depend upon the nature of the calculous diathesis.

What Dr. Prout calls the local treatment consists chiefly in prescribing hyoscyamus and opium, either alone or combined with uva ursi. The hyoscyamus, he says, is generally preferable in the lithic acid diathesis, and opium in the phosphatic. He also recommends the use of opium in the form of injection and embrocation, and especially in that of a suppository. The warm bath, fomentations, and sitting over hot water are spoken of as other means of relief.

According to the observations of the same well-informed writer, the distressing symptoms produced by lithic acid calculi have a very constant relation to the severity of the diathesis present; a circumstance which, he says, is also more or less true with respect to all the other kinds of calculi: that is to say, in proportion as the urine is unnatural, and loaded with gravel and amorphous sediments, in the same proportion are the patient's sufferings. Hence, our first object should be to restore the urine to its natural state. The first means to be recommended in ordinary cases is usually a dose of calomel and antimonial powder, the Plummer's pill, or some other alterative purgative taken at night, to be followed up the next morning by an alkaline diuretic purgative, composed, for example, of Rochelle salts and magnesia or subcarbonate of soda; during the day a strong infusion of uva ursi, combined with hyoscyamus and the liquor potassæ, may be taken. These means are to be persisted in for a greater or less time, according to the circumstances, and till the urine begins to be natural; they may then be gradually left off or varied as occasion may require; and under this plan it will be found, that, in the majority of cases, *not only the urine will assume its natural state, but most or all the distressing symptoms of calculus in the bladder will be very much diminished, and in many instances disappear.* It is obvious, also, that while the urine is in its natural state, the calculus cannot increase in size.

"After the diathesis is once fairly broken by these means, it may in general be easily prevented from recurring, by attention to the diet and other circumstances, formerly mentioned as inducing this diathesis, and by the occasional use of medicines; and the patient will scarcely know that he has a calculus in the bladder, at least from the pain that it gives him. I state this with confidence, but, at the same time, I wish to be understood to mean, that the freedom from pain, &c. depend in no inconsiderable degree upon the size of the calculus, its smoothness, upon the exercise a patient is obliged to take, &c., all of which are presumed to be favourable; for it must be sufficiently obvious, that a foreign substance in the bladder cannot be prevented from acting *mechanically*, and from occasionally producing bloody urine, or a temporary stoppage of the discharge of that secretion from the bladder, and similar symptoms, if the patient is obliged to take severe exercise."—(*Prout, On Gravel, &c. p.* 202—204.)

At the beginning of the eighteenth century lime and the alkalies were known to be frequently productive of relief in cases of stone; and in particular the nostrum of a Mrs. Steevens, the active ingredients of which were calcined egg-shells and soap, acquired such celebrity for the cures which it effected, that much anxiety was expressed that her formula should be made public. The consequence was, that in the year 1739 parliament appointed a committee of 22 respectable men to investigate the merits of the remedy in question, and, on their very favourable report, the secret was purchased for the sum of 5000*l.* These proceedings naturally interested our neighbours, and in the years 1740 and 1741, Morand communicated to the Academy of Sciences two memoirs, in which are reported numerous cases where the new remedy was tried, and mostly with success; the greater number of the patients being described as either benefited or actually cured.

In many instances, stones, which had been unquestionably felt, were no longer to be discovered; and, as the *same* persons were examined by surgeons of the greatest skill and eminence both before and after the exhibition of the medicines, it is no wonder that the conclusion was drawn, that the stones had been really dissolved. From the cessation of this success, however, and from its now being known that stones occasionally become lodged in a kind of cyst, on the outside of the general cavity of the bladder, so as to cause no longer any material suffering, surgeons of the present day are inclined to suspect that this must have happened in Mrs. Steevens's cases. This was certainly what happened to one of the persons on whom the above medicine was tried, as Dr. W. Hunter informs us. It is evident that a stone so situated would not in general produce a great deal of irritation, nor admit of being felt with a sound; though, as I have stated in the article *Lithotomy*, there have been a few exceptions to this observation.

Mrs. Steevens first gave calcined egg-shells alone; but, finding costiveness produced, she added soap. In time she rendered her process more complicated, adding snails burnt to blackness, a decoction of chamomile flowers, parsley, sweet fennel, and the greater burdock.

That in the lithic acid diathesis the carbonates of soda and potassa taken in large doses have the effect of passing into the urine, and saturating the redundant lithic acid in the unhealthy state of that fluid, is a fact decidedly proved. If there were any doubt yet remaining upon this point, it would be immediately removed by the perusal of the case of the celebrated Mascagni, as detailed by himself.—(See *Mem. della Soc. Ital.* 1804.) This eminent anatomist, being much afflicted with gravel, derived benefit from drinking the *aqua alcalina mephitica*, or Seltzer water; but conceiving that more good might result from a trial of carbonate of potash, he took at first half a drachm of this substance in the morning, and as much in the evening, dissolved in ten ounces of water. The second day the dose was augmented to two drachms, and on the third to three which quantity, dissolved in 20 ounces of water, was continued for ten days. "Before taking the carbonate of potash (says Mascagni), my urine was very acid, and immediately reddened litmus paper; as soon as the medicine was begun, I made the same experiment with the urine then voided, and found the intensity of the colour of the paper less. *The second day the paper was very little altered, and on the third the urine did not redden it at all.* The acid in my urine, therefore, was saturated, and, at the same time, the pain in my loins diminished, and no more gravel was voided with my urine. Afterward the pain ceased entirely, the urine became clearer, and I perceived that it contained an excess of potash." Being attacked again at a subsequent period with the gravel, Mascagni adopted the same treatment, and experienced equal benefit from it.

In the lithic acid diathesis, the liquor potassæ has sometimes been thought to have more efficacy than the carbonate.

Sir E. Home and Mr. Hatchet first suggested the utility of giving magnesia in cases of stone; and the proposal was communicated to the public by Mr. Brande (*Phil. Trans.* 1810). As Dr. Marcet observes, magnesia is often found advantageous in long-protracted cases, in which the constant use of the subcarbonated or caustic alkalies would injure the stomach. But he properly remarks, that if magnesia is sometimes beneficial, it has of late years often done harm. For, as this earth is the base of one of the most common species of calculi, viz. that containing the phosphate of ammonia and magnesia, there is nearly an even chance when magnesia is prescribed, without any previous knowledge of the nature of the calculus, that it will prove injurious. Magnesia also, when long and profusely administered, sometimes forms large masses in the intestinal canal, causing serious distress, and even fatal consequences.

According to Dr. Prout, purgatives will sometimes stop calculous depositions, especially in children; and Dr. Henry, of Manchester, has observed, that a quack medicine, composed of turpentine and opium, will occasionally produce a plentiful discharge of lithic acid from the bladder.

On the whole, I believe, reason and experience will allow us to consider lime-water, soap, acidulous soda water, the carbonate of potassa, the liquor potassæ, and magnesia only as palliative remedies, by which the pain of the disorder may sometimes be diminished, and the urinary secretion improved, it being more rational to impute the few supposed instances of greater success to the calculi becoming encysted.

As medicines taken into the stomach will not dis

solve urinary calculi, solvent injections have been introduced through a catheter directly into the bladder. Fourcroy and Vauquelin ascertained that a solution of potassa or soda, not too strong to be swallowed, softens and dissolves small calculi composed of the uric acid and urate of ammonia when they are left in the liquid a few days. They proved, that a beverage merely acidulated with nitric or muriatic acid dissolves, with still greater quickness, calculi formed of the phosphate of lime, and of the triple phosphate of ammonia and magnesia. They also ascertained that calculi composed of the oxalate of lime, which are the most difficult of solution, may be softened, and almost quite dissolved, in nitric acid greatly diluted, provided they are kept in the mixture a sufficient time.

Liquids are then known which will dissolve calculi of various compositions; but, as I have already hinted, much difficulty occurs in employing them effectually in practice. For, although they can be easily injected into the bladder, this organ is so extremely tender and irritable, that the action of such liquids upon it, as would be requisite for dissolving a stone, would produce sufferings which no man could endure, and the most dangerous and fatal effects on the bladder itself. Another objection to this practice also arises from the surgeon never knowing what the exact composition of a calculus is before this body is extracted, and his consequent inability to determine what solvent ought to be tried.

Until the complete success of lithontriptics is established, therefore, the operation of lithotomy, severe and hazardous as it is, must continue an indispensable practice, wherever the patient's sufferings are great, and the calculus too large to be voided or extracted through the urethra, or the circumstances such as to prevent the successful application of the lithotritic instruments devised by M. Le Roy D'Etiolles, Dr. Civiale, and Baron Heurtelour, and which are calculated to reduce the calculus to powder or small particles, so that it may be discharged with the urine.—(See *Lithontriptor.*) The great success, however, that has attended this practice in France, justifies a confident hope that it will soon have the effect of materially diminishing the number of operations in England as well as in other countries. Children are conceived not to be favourable subjects for it, on account of the small diameter of their urethra and their unmanageableness. It is also alleged, that as lithotomy is very successful upon young subjects, lithotritic attempts are not requisite. Doubts may be entertained, however, of the soundness of these views; for cases are on record, where the stone was most effectually crushed, and voided from children. Though in them the urethra is narrow, still it may be gradually dilated, and its shortness in some measure compensates for its little diameter. If also it be generally the fact that children bear lithotomy more safely than adults, it is far from being true that such is the great success of the operation on them, that the application of lithotritic plans to them is scarcely a desideratum. Sometimes very old subjects are so reduced by the long-continued irritation and excruciating agony of stone, that it is argued that their situation will not admit of delay, and that lithotomy should here be preferred as the quickest means of relief. In defence of this view of the subject, it is also urged, that in many old persons the bladder contracts so feebly, that if the calculus were crushed or ground to powder, they would not be able to expel the fragments or particles. No doubt the lithotritic art, at least in its present state, must have restrictions; but it is rational to believe, that it is yet susceptible of improvement, and that as this takes place, the number of cases to which it will become applicable will considerably increase. As things are, I regard it as an invention of the highest importance to mankind, and reflecting immortal honour on the several ingenious men by whose industry and talents it has been made capable of doing what it has already done. In the early stage, before calculi have exceeded a certain size, if they cannot be expelled with the urine, they may sometimes be taken out by means of the urethral forceps invented by Mr. Weiss, of the Strand: this instrument is shaped like a sound, but its end, after introduction into the bladder, admits of being opened and made to grasp the calculus, which is then to be drawn through the urethra. The urine is first to be discharged through a catheter.—(See *an Account of a Case, in which numerous Calculi were extracted without cutting Instruments, by Sir A. Cooper, in Med. Chir. Trans. vol.* 11, *p.* 349. Also, *Lithotomy.*)

URINARY FISTULÆ. By a urinary fistula is implied a deep, narrow ulcer which leads into some of the urinary passages. If, however, as is alleged, the fistula after a time becomes lined by a kind of membrane resembling a mucous membrane (see *Stafford on Strictures, p.* 39, *ed.* 2), it is not strictly correct to describe the whole fistula as an *ulcer*, though its orifice may really have this character. The application of this name to sinuses, which do not communicate with these passages, but only terminate near some point of their course, appears to me rather absurd. One of the chief circumstances tending to evince that a sinus has no communication with the urethra is, that no urine has ever escaped through the opening; for, with respect to the judgment formed from the impossibility of making a probe touch a catheter in the passage, it must be exceedingly fallacious, because the winding course of the sinus or the small size of its communication with the urethra, may prevent the instruments from touching each other.

According to Desault, the indications in the treatment of such a case depend upon the nature of its complications. When the sinuses are kept up by a separation of the scrotum from the parietes of the urethra, Desault recommends exact compression to be made over the part, which method, he says, is sometimes sufficient to accomplish a cure. When this plan fails, he states, that the healing of the sinus may be pro-

moted by practising an incision on one side of the scrotum, and carrying it as far as the denuded portion of the urethra. When sinuses exist, and they depend upon the smallness of the opening, or its unfavourable situation for the discharge of the matter, the aperture should be enlarged by making an incision into the main collection of pus. When there are callosities, which resist cataplasms and the most active resolvents, Desault advises us to introduce into the fistula trochees of minium, for the purpose of destroying the indurated parts; a plan that has long been relinquished. When the bones are diseased, exfoliation must be awaited; and, in every instance, the treatment should vary according to the cause upon which the fistula depends.

Fistulæ communicating with the urethra, but having no external opening, are sometimes produced in consequence of the bursting of an abscess into this canal; the ulceration from a retention of urine; a false passage; and the healing of the external part of the wound made in lithotomy while the internal part is not united.

In these cases, there is a discharge of pus from the urethra before, and sometimes after, the issue of the urine; and one may feel, in the course of the urethra, a tumour which increases while the patient is making water, and afterward disappears on pressure, attended with a fresh discharge from the penis of a mixture of pus and urine.

These internal urinary fistulæ cannot be cured except by preventing the urine from passing into them and lodging there. The catheters employed should be neither too large nor too small. If too large, they would exactly fill the canal, and the pus and urine contained in the fistulæ could not be discharged. If too small, the urine would insinuate itself between them and the sides of the urethra and enter the fistulæ. Their use must be continued till the ulcer is entirely healed.

The most frequent urinary fistulæ are those which are termed *complete*. Their origin may be in the ureters, bladder, or urethra. Those which arise in the ureters sometimes terminate in the colon, and the urine is discharged *per anum* mixed with the feces. But most commonly they make their appearance externally, either in the lumbar or inguinal regions. Those which communicate with the bladder, have also different terminations. When they proceed from the upper and interior part of this organ, they ordinarily pierce the parietes of the abdomen above the pubes and towards the navel. They also sometimes terminate in the groins. When they originate in the posterior parietes of the bladder, they sometimes tend into the cavity of the abdomen, where they almost always prove mortal; and sometimes into the intestines, if there should be adhesions between these and the bladder, so as to favour this communication. When the opening in the bladder is near the bottom of this viscus, the fistula sometimes terminates in the rectum of the male and the vagina of the female subject; but most frequently it ends in the perinæum in both sexes. With regard to the fistulæ, which originate in the urethra, they usually open externally in the perinæum, the scrotum, or the penis, and sometimes also in the rectum. It is not uncommon to see the external opening of these fistulæ at a great distance from the internal one, and to find it in the middle and even the lower part of the thighs, the groins, parietes of the abdomen, and as high as the sides of the chest. Often there is only one opening in the urethra, while there are several situated externally, more or less distant from one another.

Most of these fistulæ are the consequences of a retention of urine, and owing to the same causes as the diseases of which they are a symptom. Those which communicate with the rectum, in the male subject, sometimes depend upon this intestine having been wounded in the operation of lithotomy. Those which open into the vagina are often the effect of a violent contusion, caused by the head of the child in difficult labours, or of ulceration produced by pessaries which are too large, and the margins of which are too sharp and irregular. Carcinoma of the rectum and vagina also give rise to fistulæ, by extending into the bladder.

The discharge of urine from the external orifice of the fistula is an unequivocal proof of its communication with the urinary passages: when the fistula is narrow, and there is no obstruction in the urethra, the urine sometimes escapes more readily the latter way than through the fistula. It may also be difficult, or even impossible, to find out the internal orifice of the fistula with a probe. When the fistula communicates with the rectum or vagina, a staff introduced through the urethra may sometimes be felt in those parts.

When fistulæ of the bladder or urethra are the consequences of a retention of urine, produced by strictures which still exist, or have even increased since the formation of the fistulæ, the circumstance may render the introduction of the catheter difficult. In this sort of case, if the catheter cannot be passed, the surgeon must endeavour to remove the stricture with bougies or other instruments, on the principles explained in the article *Urethra, Strictures of*. "In general (as Sir Everard Home observes), where fistulæ take place in perinæo, in consequence of a stricture, the removal of the stricture is sufficient to give the fistula a disposition to heal. There are, however, cases which require more being done for that purpose, and simply laying them open is not sufficient."—(See *Fistulæ in Perinæo.*) Under such circumstances he finds the actual cautery the surest means of making the part heal. In one case, he passed a bougie into the urethra, and seared the edge of the fistula with a hot wire, introduced as far as to touch the bougie. In another instance, a full-sized silver sound was passed into the bladder, and, the direction of the fistula having been ascertained with a probe, a female steel sound was heated to redness, and "at the moment at which it passed from a red to a black heat, it was hurried down through the fistula (about two inches and a half) to the sound in the urethra." In both these cases a cure was effected.—(*Home on Strictures, vol. 3, p. 262, &c.*) According to my experience, at least nine urinary fistulæ out of ten are the consequences of strictures in the urethra.

When fistulæ terminate in the lower part of the bladder, Desault advises the utmost care to be taken to prevent the catheter from being stopped up, and to hinder the instrument from becoming displaced, or slipping out of the bladder; for which last purpose, the catheter bracelet, described by Sir E. Home, seems well calculated. However, when the fistula communicates with the urethra, Desault believes, that no advantage would be derived from keeping the catheter open. In both cases, he recommends us to continue the catheter, not only until the fistula is cured, but also until the obstacles, which hinder the urine from passing the natural way, are removed.

Fistulæ of the bladder, communicating with the vagina, and produced by difficult labours, are almost always attended with loss of substance. The forcible contusion, occasioned by the child's head on the anterior parietes of the vagina and bottom of the bladder, gives rise to the formation of sloughs, the separation of which sometimes leaves apertures large enough to admit the finger, and hence the difficulty of the cure. In treating such fistulæ, there are two indications to be fulfilled: 1st, to hinder the urine from passing into the vagina; 2dly, to keep the edges of the division as closely as possible together, so as to give them an opportunity of uniting.

In women, the introduction of the catheter is easy; but the instrument is more difficult to be fixed, than in men. Desault contends, however, that it is very essential to have it so fixed in the bladder, that the urine may escape. He found, that the only effectual plan was to fasten the catheter to a point, that always retained the same position, with respect to the meatus urinarius. He used a kind of machine, made after the manner of a truss, the circle of which was long enough to embrace the upper part of the pelvis, and had in its middle an oval plate, intended to be placed upon the pubes. In the centre of this plate was a groove to which a piece of silver was fitted, curved so that one of its ends, with an aperture in it, came over the vulva, on a level with the meatus urinarius. This piece of silver admitted of being fastened to the plate with a screw. After the catheter had been introduced and arranged in the bladder, so that its beak and eyes were situated at the lowest part of this viscus, the end of the instrument was put through the aperture of the piece of silver, which slided into the groove of the plate, and it was afterward fixed in the way already explained. By means of this machine, the catheter was securely fixed, without incommoding the patient, even when she was walking

In these last cases, large catheters, with full-sized apertures, should be employed, so that the urine may more readily escape through the instrument, than fall into the vagina. In the early part of the treatment, the catheters should also be left constantly open.

In order to keep the edges of the division as near together as possible, Desault introduced into the vagina a soft kind of pessary, large enough to fill the vagina, without distending it. By this means, the form of the fistula was changed from round to oval, which is the most favourable to its reunion; and the advantage was gained of closing the fistula, and hindering the urine from falling into the vagina. The efficacy of the catheter, when properly fixed, has lately been illustrated in an interesting case, published by Dr. Cumin, of Glasgow, who considers the introduction of the pessary into the vagina useless and objectionable.—(See *Edin. Med. Journ. No.* 78, *p.* 62—64.)

When the rectum is wounded in lithotomy, Desault advised dividing the parts, comprehended between the wound of the operation, the opening in the rectum, and the margin of the anus. That such an operation may become necessary in some instances, I will not say; but, it can never be proper, until it is seen whether the wound of the rectum will not heal up favourably, without such treatment. I have seen two cases, in which the rectum was cut in lithotomy, yet no fistula ensued; and other similar facts have been mentioned to me by professional friends. The success, also, with which the wound has generally been healed after lithotomy, done through the rectum, is another fact tending to prove that the inconveniences of a wound of the latter bowel in the operation have been rather exaggerated.

In a case of urinary fistula, communicating with the rectum, and which could not be healed with the catheter, Sir A. Cooper introduced a catheter into the bladder, and his finger into the rectum, and then made an incision, as in the operation for the stone, in the left side of the raphe, until he felt the staff through the bulb. He then directed a double-edged knife across the perinæum, between the prostate gland and the rectum, with the intention of dividing the fistulous communication between the urethra and the bowel. A piece of lint was introduced into the wound, and a poultice applied. When the lint was removed, the urine was found to take its course through the opening in perinæo; the aperture in the rectum gradually healed; and that in the perinæum quickly closed; the urine being all now discharged in the natural way.—(*A. Cooper, Surgical Essays, part* 1, *p.* 215.)

As the same gentleman has observed, apertures in the urethra, attended with loss of substance, are extremely difficult to heal. He relates a case, where the urethra had sloughed at the junction of the scrotum with the penis: the opening healed at its margin, but a large fistulous orifice still remained. Bougies, the plans of excoriating the edges of the opening with blistering plaster, and even paring them off, and bringing the fresh-cut surfaces together with the twisted suture, had all been tried in vain. In this example, a cure was effected by applying the nitrous acid to the edge of the fistulous orifice, and to the skin, three-quarters of an inch around it, the principle on which Sir A. Cooper rested his hopes of success being the contraction of the skin in cicatrization. The first application having produced considerable amendment, the plan was repeated several times in the course of about nine months, at the end of which time, the fistula was closed. He is of opinion, that such practice will only succeed in cases where the skin is very loose, and the scrotum forms a part of the fistulous orifice. If the skin be much confined, he suggests raising a piece of skin from the scrotum, paring off the edges of the fistulous orifice, and removing the skin to a small extent around it. The skin thus raised is to be turned half round, so that its raw surface may be applied to the opening, and unite. An elastic catheter is first to be introduced. In the successful operation of this kind, which was actually done, the flap was held by four sutures; and small slips of adhesive plaster, and a bandage to support the scrotum, were employed. In the course of the treatment, pressure was found necessary to prevent the occasional passage of urine through the wound.—(*A. Cooper, Surgical Essays, part* 2, *p.* 221, *&c.*

Mr. Earle met with a case, in which the integuments in the perinæum, and above an inch of the canal of the urethra, had sloughed away, in consequence of external violence. At the man's entrance into St. Bartholomew's Hospital, a large smooth cicatrix occupied the place of the urethra, no vestige of which remained in that part. The integuments on the right side had suffered less extensively than those on the left; so that when the catheter was introduced, that portion of the instrument, which passed over the cicatrix, could be about half covered, by drawing the skin and healed part from the right, towards the opposite side. The treatment was therefore begun by confining the knees together over a pillow, and applying a kind of truss, which kept the skin constantly pressed towards the left side. While these measures were going on, the opportunity was taken of dilating the anterior portion of the urethra with bougies. Afterward the following operation, which I had the pleasure of seeing, was performed: a portion of the integuments was removed about an inch and a half long, and one-third of an inch in width, on the left side of the cicatrix. The groove thus formed, was intended for the reception of the edge of the skin to be detached from the opposite side An incision was then made across the perinæum, above and below, so as to pare away the callous edges of the urethra. The skin was next dissected off from a portion of integument on the right side of the perinæum, about an inch and a half in length, and half an inch broad, leaving a smooth space of rather more than an inch between the cut surfaces. The integuments, on the right side, were now dissected up, turned over a catheter, and brought in contact with the opposite groove. The detached portion of cicatrix bled little during the operation; and before it could be applied to the groove, its edge had so livid an appearance, as to create an apprehension that it must perish. Two sutures were employed to assist in retaining it in the desired position, and some straps of adhesive plaster, and a bandage, completed the dressings. The day after the operation, it was evident, that some urine had escaped by the side of the catheter; and, on the third day, when the dressings were removed, it was found, that the portion of flesh which had been deprived of skin had sloughed, but that a sufficient quantity had united, above and below, to form a canal, open at one side, and large enough to include the whole catheter. After the parts had healed, some urine could be made to pass through the urethra, when pressure was applied to the left side of the remaining fistula. Various attempts were afterward made to excoriate its edges, and unite them, but without success.

A second operation was therefore done in the summer of 1820, and integuments were now borrowed from the opposite side to that from which they had been taken in the first operation. "A deep groove was made on the right side, the surface was denuded of its cutis to some extent, a considerable portion of integument was then detached from the left side, and, in order to obtain healthy skin (says Mr. Earle), I encroached a little on the thigh, and laid bare the edge of the fascia lata. Instead of passing any ligature through the detached portion, the old quill-suture was employed, which was passed from the two outer cut surfaces. A pad of adhesive plaster was interposed between the ligatures and the flap of skin." The catheter was not left in the urethra, but introduced about three times in 24 hours. By this operation, much more was gained, and about two-thirds of the deficient part of the canal were restored: but still a small aperture remained at the upper part. This opening could not be closed by touching it with escharotics, and, consequently, a third operation on a smaller scale was done, which so nearly completed the cure, as to leave only an orifice large enough to admit a bristle, and this opening subsequently closed, and the patient remained quite well in March, 1821.—(See *Phil. Trans. for* 1821.)

Here we see the same art, by which new noses and under lips are formed, extending itself to cases, where it may be the means of extricating some individuals from a state in which life is hardly desirable. The surgeon of judgment, however, will never forget, that such an operation is only indicated where the fistula is large, the urethra free from obstruction, and bougies and the catheter insufficient.

URINE, INCONTINENCE OF. This complaint is quite the reverse of retention of urine; for, as in the latter affection the urine is continually flowing

into the bladder, without the patient having the power to expel it; so, in the former, it flows out, without the patient being able to retain it.

According to Desault, children are particularly liable to the disorder; adults are less frequently afflicted with it; and persons of advanced years appear to be still less liable to it. The last observation may seem an error to such practitioners as have met with numerous examples, where patients advanced in years were incapable of retaining their urine. The fact is, that the overflow of this fluid, or, in other words, its dribbling away through the urethra, in some cases of retention, of which it is only a symptom, has been too commonly confounded with an incontinence of urine, though the cases are as different in their nature as possible, and require very opposite modes of treatment. *In retentions, depending upon weakness and paralysis of the bladder, the involuntary dribbling of the urine* is generally only an effect of the other disease, and they prevail together. The distended bladder reacts upon the urine, and forces some of it out of the urethra, until the resistance of the sphincter and of the urethra are precisely equal to the expelling power. Sometimes the urine even dribbles away incessantly, as is found to happen when the action of the bladder is entirely destroyed; for, being then constantly full, it cannot hold any more of the urine descending to it through the ureters, unless as much be voided through the urethra as is received from the kidneys, and as unremittingly as the addition from the latter organs continues to be made. Such a case rather belongs to the article, *Urine, Retention of*, than the present subject.

It is correctly remarked by Desault, that the causes of an incontinence of urine, strictly so called, are the very reverse of those of a retention. The latter case happens whenever the action of the bladder is weakened, and the resistance in the urethra increased. On the contrary, an incontinence originates either from the expelling power of the bladder being augmented, while the resistance in the urethra is not proportionately increased, or from the resistance being lessened while the expelling force continues the same. On these principles, Desault thought it easy to explain why the disorder should be most common in children; and one reason which he gives for the circumstance is, that in childhood there is more irritability than at any other period of life. The expulsion of the urine, he observes, is entirely effected by muscular action, while the resistance is merely owing to the sphincter vesicæ, the levatores ani, and perhaps to a few other inconsiderable fasciculi of muscular fibres; for the different curvatures of the urethra and the contractile power of this tube itself, he thought, could make only a feeble resistance to the discharge of the urine. An incontinence happens in children, because the bladder contracts so suddenly and forcibly that its contents are voided almost before these young subjects are aware of the occasion to make water, and without their being able to restrain the evacuation. There are also many children who, from indolence or carelessness, do not make water immediately the first calls of nature invite them, and who afterward, being urgently pressed, wet their clothes. In other young subjects, the sensation which makes the bladder contract and accompanies the expulsion of the urine is so slight, that the function is performed without any formal act of the will, without even exciting an impression sufficiently strong to disturb sleep. This is the case with such children as are troubled only with an incontinence of urine in the night-time. Increasing years, by diminishing the irritability of the bladder and making man more attentive to his necessities, usually bring about a cure of the infirmity, which seldom continues till the patient has attained the adult state.

It was not, however, the doctrine of Desault, that no period of life excepting childhood is subject to incontinence of urine. On the contrary, he admits that other ages are subject to it; but then it depends almost always upon a want of resistance to the escape of the urine. Thus, it may be occasioned by weakness, or paralysis of the sphincter vesicæ, or levatores ani; sometimes also by a forcible dilatation of the urethra, and loss of its elasticity, and (as Desault might have added) its muscular power of contraction, since the microscopical observations of Mr. Bauer tend to confirm the existence of muscular fibres on the outside of the membrane of the canal, though, as is elsewhere mentioned, their arrangement and mode of action are now represented to be quite different from what was formerly supposed.—(See *Urethra, Strictures of the.*)

A calculus, a fungus, or any other extraneous body of an irregular shape, may lodge in the neck of the bladder, but, not accurately filling it, may allow the urine to escape at the sides; or there may even be in the calculus grooves through which the urine may pass into the urethra.

A violent contusion, or forcible distention of the sphincter, is often followed by an incontinence of urine. Formerly, the complaint used to be very common after the mode of lithotomy called the apparatus major, and it is even at present not an unusual consequence of the extraction of calculi from females, either by dilatation or division of the meatus urinarius and neck of the bladder.

Women, after difficult labours, and in whom the child's head has seriously contused and weakened the neck of the bladder, are also subject to a species of incontinence of urine; which, however, is in general experienced only when they laugh, or make exertions.

Incontinence of urine is stated by many writers to be an attendant on palsy and apoplexy. Here they mistake what the French surgeons aptly call the "*retention d'urine avec regorgement,*" for an incontinence. In such cases, the involuntary discharge of urine has been referred to paralysis of the sphincter of the bladder; but, it is forgotten that the bladder itself also participates in the paralytic affection; for the sphincter not being a particular muscle, but only a fasciculus of fleshy fibres, formed, as Desault observes, by the junction of those which compose the inner layer of the muscular coat of the bladder, it can only be weakened in the same degree and at the same time as the rest of this organ. Besides, says Desault, it is proved, and all physiologists admit the fact, that the action of the bladder is absolutely necessary for the expulsion of the urine, and that when this organ cannot act, a retention always ensues. Although much less danger attends an incontinence than a retention of urine, the infirmity is a serious affliction; for, as the patient's clothes are continually wet with a fluid that readily putrefies, the stench which he carries about with him is offensive to himself and every body who approaches him.

In children, the disorder usually gets well of itself, as they grow up and acquire strength. When they wet their beds really from idleness and carelessness, moderate chastisement may be proper, inasmuch as the fear of correction will make them pay more attention to the earliest call to make water. However, it has always been my own belief that this doctrine is carried to an unjustifiable extent, particularly in schools, and been a pretext for the most absurd kind of severity. Nor is it doubted by any man who understands the subject, that in almost all cases the disorder is a true infirmity arising from the causes already indicated, and not from indolence; the supposed crime taking place, in fact, when the child is asleep and unconscious of what is happening.

If excessive irritability and constitutional weakness be the cause of incontinence of urine, and a very small quantity of urine forces the bladder to contract, the resistance of the urethra being involuntarily overcome, an endeavour should be made to lessen such irritability by the use of the warm or cold bath, sea-bathing, tonics, chalybeates, good air, &c. And in order to prevent the accident from taking place in the night-time, the child should not take any drink for some time before being put to bed, the bladder should be always emptied before sleep, and, if necessary, the child ought to be taken up in the night for the same purpose.

If the infirmity arises from a want of action in the parts, causing the resistance in the urethra, tonics may be externally and internally employed. However, when the disorder has been of long standing, Desault found that they rarely succeeded.

Palliative means are then the only resource; viz. instruments calculated either to compress the urethra and intercept the passage of the urine, or to receive the fluid immediately it is voided. The first of these plans is more difficult to accomplish in women than men; but it may be executed by means of an elastic hoop which goes round the pelvis, and from the middle of which, in front, a curved elastic piece of steel descends, and terminates in a small compress, which is

contrived to cover accurately the mentus urinarius.—(See *Œuv. Chir. de Desault, par Bichat, t.* 3; *p.* 95, *&c.*)

Large blisters applied over the os sacrum have often cured an incontinence of urine, both when the complaint seemingly arose from the excessive irritability of the bladder, and from paralysis and loss of tone in this organ and the parts, which naturally resist the expulsion of the urine from it; the case being, in fact, a retention "par regorgement," or, as one might call it in plain English, a retention combined with incontinence of urine.—(See *Med. Obs. and Inq.*) As in some of these cases the blisters removed also a paralysis of the lower extremities, they might have furnished a hint to the practice of making issues for the relief of the palsy of the legs, connected with diseased vertebræ. Cantharides have also been given inwardly with success.—(See *Journ. de Méd. t.* 55, *p.* 72; and *Howship on Diseases of the Urinary Organs*, *p.* 205.)

URINE, RETENTION OF. It is observed by the experienced Mr. Hey, that a retention of urine in the bladder, when the natural efforts are incapable of affording relief, is in male subjects a disease of great urgency and danger. Persons advanced in years are more subject to this complaint than the young or middle aged. It is often brought on by an incautious resistance to the calls of nature, and, if not speedily relieved, generally excites some degree of fever.

The distinction, says Mr. Hey, which has sometimes been made between a *suppression* and *retention* of urine, is practical and judicious. The former most properly points out a defect in the secretion of the kidneys; the latter, an inability of expelling the urine when secreted.

The *retention of urine* is an inability, whether *total* or *partial*, of expelling by the natural efforts the urine contained in the bladder. The characteristic symptom of this disease, previous to the introduction of the catheter, is a distention of the bladder (to be perceived by an examination of the hypogastrium), after the patient has discharged *all* the urine which he is capable of expelling.

As this complaint may subsist when the flow of urine from the bladder is by no means totally suppressed, great caution is required to avoid mistakes.

Violent efforts to make water are often excited at intervals, and during these strainings small quantities of urine are expelled. Such a case may be mistaken for strangury.

At other times a morbid retention of urine subsists, when the patient can make water in a stream, and discharge a quantity equal to that which is commonly discharged by a person in health. Under this circumstance, Mr. Hey has known the pain in the hypogastrium and distention of the bladder continue till the patient was relieved by the catheter.

And, lastly, it sometimes happens that when the bladder has suffered its utmost distention, the urine runs off by the urethra as fast as it is brought into the bladder by the ureters. Mr. Hey has repeatedly known this circumstance cause a serious misapprehension of the true nature of the disease.

In forming a correct judgment of all these cases, it is very necessary to recollect the important division of retentions of urine into the *complete* and *incomplete* forms; a distinction which will at once put the surgeon on his guard against a variety of errors.

In every case of retention of urine which the late Mr. Hey had attended, the disease could be ascertained by an examination of the hypogastrium taken in connexion with the other symptoms. The distended bladder forms there a hard and circumscribed tumour, giving pain to the patient when pressed with the hand. Some obscurity may arise upon the examination of a very corpulent person; but, in all doubtful cases, the catheter should be introduced.

Mr. Hey has not adverted to the swelling in the rectum or vagina, nor to cases of contracted bladder, where, of course, the information derived in ordinary instances from the tumour above the pubes cannot be had; but, in other respects, his observations on the diagnosis are practical and correct. He had seen only a few cases of *ischuria renalis*, or complete suppression of the secretion of urine. The disease proved fatal in all his patients except one, in whom it was brought on by the effect of lead taken into the body by working in a pottery. It subsisted three days during a violent attack of the colica pictonum, and was then removed, together with the original disease. Mr. Hey found no difficulty in distinguishing this disorder in any of the cases from the *ischuria vesicalis*; though, for the satisfaction of some of his patients, he introduced the catheter.—(*Pract. Obs. in Sur. p.* 374, *&c.*)

Retention of urine may be the effect of a great many different causes; as paralysis of the bladder; inflammation of its neck; the presence of foreign bodies in it; pressure made on its cervix by the gravid uterus; enlargement of the prostate gland; strictures in the urethra, &c.

Every case of retention of urine demands prompt assistance; but when the disorder presents itself in its complete form, the mischief of delay is of the most serious nature; for if the bladder remain preternaturally distended, it not only loses its contractile power, but is quickly attacked with inflammation and sloughing. At length some point of it bursts, and the urine is extravasated in the cellular membrane of the pelvis; spreading behind the peritoneum as far up as the loins, and, in other directions, into the perinæum, scrotum, and the integuments of the penis, and upper part of the thighs. The common result then of the rupture of the bladder and the effusion of its contents, is the speedy death of the patient, from the effects of this irritating fluid upon all the parts with which it comes in contact, among which effects is inflammation of the peritoneum and bowels. It appears also from the observations both of Desault and Sir Everard Home, that a complete retention of urine, after a time, has the effect of putting a mechanical stoppage to the farther secretion of this fluid in the kidneys; a circumstance which sometimes has a principal share in producing death, particularly when this event happens before the urine becomes extravasated.

In all cases of retention of urine, the indications are sufficiently manifest, viz. 1st. To adopt such treatment as seems best calculated to procure a discharge of the urine through the natural passage, which object is performed sometimes by means of fomentations, the warm bath, bleeding, opium, and other medicines; sometimes by the removal of mechanical obstacles to the flow of the urine; but more frequently by the use of the catheter than any other means. When all these plans fail, it then becomes necessary to puncture the bladder. 2dly. The second indication, or that which presents itself after the immediate dangers of the distention of the bladder, are thus guarded against, is, to remove whatever disease, or other circumstance, constitutes the still existing impediment to the natural expulsion of the urine.

With respect to the fit manner and time of employing the several means for fulfilling the above indications, and the selection which should be made of them, these are important considerations, which vary in different cases, and actually cannot be understood without due reference to the causes and circumstances of each individual case. Some of this subject belongs also to other parts of this work, to which, in order to avoid the necessity of repetition I here refer.—(See *Catheter; Bladder, Puncture of; Prostate Gland, Diseases of; Urethra, Strictures of, &c.*)

With respect to catheters, we shall find that some cases require the urine to be drawn off two or three times a day, and the instrument to be taken out after each evacuation; while in other instances it is prudent to keep the tube continually introduced. Here one general caution may be conveniently offered, which is, never to let a silver catheter remain in the passage more than a week or ten days without taking it out and cleaning it; for if this be not done, the instrument becomes coated with deposites from the urine, so as afterward not to admit of being withdrawn through the urethra without great suffering and irritation. The eye in the beak is also apt to become completely blocked up; and sometimes the pressure which the catheter makes on the part of the urethra, corresponding to the root of the penis, in front of the scrotum, causes in this situation inflammation, followed by a slough as large as a crown piece, and an opening formed by the loss of substance is left, which may even continue fistulous during the patient's life. These remarks particularly apply to metallic catheters; but such as are supposed to be made of elastic gum, especially those ordinarily met with in the shops, are apt to spoil and become blocked up with mucus, if not taken out and cleaned or changed every five or six days. However

as I have mentioned in the article *Prostate Gland, Diseases of*, Mr. Weiss has succeeded in constructing elastic catheters which may be retained more than a fortnight in the urethra without becoming obstructed, besides having the advantage of always retaining a due curve.

1. *Of the Retention of Urine, to which persons of advanced age are liable.*—This disorder is so common in elderly persons, that it is generally allowed to be one of the grievances to which their period of life is particularly exposed. In them the bladder is less irritable than in younger subjects, and hence it is not so soon stimulated by the presence of the urine. In fact, it is not until a painful sensation arises from the distention of the coats of the bladder, that the patient is aware of the occasion to discharge the urine. The bladder then contracts; but still would not be able to expel its contents were it not for the powerful action of the abdominal muscles. Nor is the expulsion of the urine even now complete; since the bladder no longer retains the power of effacing the whole of its cavity. On the contrary, after each evacuation, some urine is still left undischarged, and already constitutes an incipient retention. The quantity daily augments, and at length not more than half the fluid contained in the bladder is voided at each evacuation.

The complaint particularly attacks old subjects of a plethoric state of body, and of sedentary and studious habits. It also especially afflicts those who, from carelessness or indolence, do not take time enough to expel the last drops of urine; and others, who are accustomed to discharge their urine into a pot, as they lie in bed, instead of rising for the purpose.

In these cases, the urethra and neighbouring parts seem to be free from every disease capable of preventing the issue of the urine; which has always come away freely and in a full stream, although it could not be discharged with the same force nor to the same distance as formerly. At length, instead of describing an arch as it flows out, it falls down perpendicularly between the legs. Towards the close of the evacuation, the patient is also not sensible of the final contractile effort of the bladder, of which he used to be conscious in his younger days. When he is about to make water, he is obliged to wait some time before the evacuation commences; and as the disorder increases, he cannot make water without considerable efforts; the quantity of urine voided each time manifestly decreases; the desire to empty the bladder becomes more and more frequent; and lastly, the urine only comes away by drops and an incontinence succeeds a retention.

In this state, the patient's sufferings are not very great. The tumour formed by the bladder above the pubes is indolent, and if it be pressed upon with some force, a certain quantity of urine is discharged from the urethra.

The retention of urine arising from old age is seldom complete: the urine, after having filled and distended the bladder, dribbles out of the urethra, so that the patient voids as much of this fluid in a given time as he does in a state of health. Nor is this species of retention of urine commonly attended with very urgent symptoms. It does not occasion, like complete retention, a suppression of the urinary secretion in the kidneys; and as the urine escapes through the urethra after the bladder is distended to a certain degree, the disorder is less apt to produce a rupture of this organ, and dangerous extravasations of the urine. The swelling of the bladder then continues, without any particular suffering, except a sense of weight about the pubes and perinæum. These circumstances have often led to serious mistakes, and the disease has been set down as an abscess or dropsy.

The indications are, to evacuate the urine and restore the tone of the bladder. When the retention is incipient, the proper action of the bladder will sometimes return after cold applications are made to the hypogastric region or thighs, and the patient goes from a warm into a cool place in order to make water.

The patient must also be strictly careful to make water immediately the least inclination to do so is felt; for if this precaution be neglected, the bladder grows more and more inert; the desire to make water subsides; and the retention, which at first consisted of only a few drops, very soon becomes complete. It would then be in vain, as Desault observes, to try the expedients above recommended No stimulus will now make the bladder contract sufficiently to expel the whole of the urine, and the catheter is the only thing by which this fluid can be discharged. This artificial mode of evacuation, however, only affords temporary relief; for, as the bladder is slow in recovering its tone, a relapse would be inevitable if the employment of the catheter were not continued. Hence this instrument must either be left in the bladder or introduced as often as the patient has occasion to make water. When a skilful surgeon is constantly at hand, or when the patient knows how to pass the catheter himself, Desault thinks it better to introduce the instrument only when the bladder is to be emptied, by which means the inconvenience arising from the continual presence of a foreign body will be avoided. In this case, either a silver catheter or an elastic gum one may be used with equal advantage; but if the instrument is to be kept in the bladder, one made of elastic gum and provided with a curved stilet is to be preferred. As in old subjects the urethra is flaccid, a large catheter is generally found to enter more easily than one of smaller diameter.

As the treatment must be continued for a long while, and the bladder seldom perfectly regains its tone in old age, the patient should be instructed how to introduce the catheter himself, and he is to pass it whenever he wants to make water. After a certain time, however, he may try if he can empty the bladder without this instrument. When he finds that he can expel the urine, he should assure himself, by means of the catheter, that the last drops of this fluid are duly voided. Should they not be so, he must persevere in the use of the instrument.

In this sort of retention of urine, it has been proposed to throw into the bladder astringent injections: Desault tried them; but he does not give a favourable report of the practice.

Warm balsamic diuretic medicines, cold bathing, and liniments containing the tinctura cantharidum, have likewise been praised; but, according to Desault, these means frequently prove hurtful to persons of advanced years, and are seldom useful. He restricted his own practice to the use of the catheter, which, when skilfully employed, often restored the tone of the bladder, and, when it failed, other means also were ineffectual. A blister over the sacrum may deserve a trial.

Passing over the cases of retention of urine, referred by Desault to the effects of intemperance with women, and the immoderate use of diuretic drinks; cases which considerably resemble, in their nature and treatment, the retention from the weakened state of the bladder in elderly persons; I proceed to another example of the disorder, still more interesting to the practical surgeon.

2. *Retention of Urine from an Affection of the Nerves of the Bladder.*—These nerves may be affected either at their origin, or in the course of their distribution. Injuries of the brain are seldom followed by a retention of urine; but the complaint often accompanies those of the spinal marrow. A concussion of this medullary substance from blows or falls upon the vertebral column; the injury which it suffers in fractures and dislocations of the vertebræ, or from a violent strain of the back; its compression by blood, purulent matter, or other fluid effused in the vertebral canal, and the effects which a caries of the spine has upon it; may all operate as so many causes of a retention of urine. This form of the complaint may also be the consequence of tumours situated in the track of the nerves, which are distributed to the bladder. Whether the retention of urine, common in typhus fever, arises from an affection of the nerves of the bladder, or from the general debility extending itself to the expelling powers, may be a question; but the liability of patients in fevers to this disorder should never be out of the practitioner's recollection.

When a retention of urine arises from injury or disease of the spinal marrow, an insensibility and weakness of the lower extremities are almost always concomitant symptoms. The patients suffer very little; most of them are ignorant of their condition; and do not complain of any thing being wrong in the functions of the urinary organs. The surgeon, aware that a retention of urine is common in these cases, should examine whether there is any interruption of the evacuation, either by feeling the state of the abdomen just above the pubes, or by introducing a catheter.

As this species of retention of urine is only symptom

atic, and not dependent upon any previous defect in the bladder, it is not in itself alarming; but, with reference to its cause, it is exceedingly dangerous. Affections of the spine complicated with injury of the spinal marrow, are often fatal. By means of a catheter, it is always easy to relieve the inconveniences arising from the bladder not contracting, and thus fulfil the only indication which this sort of retention of urine presents; viz. the evacuation of the urine. But this proceeding is merely palliative; and the bladder will not recover its contractile power until the causes of its weakness are removed. The last then is the main object in the treatment, which must vary according to the nature and extent of the disorder.

The consideration in detail of all the means which may be requisite for the relief of the different accidents and diseases of the spine, belongs to other parts of this work.—(See *Dislocations and Fractures of the Vertebræ; Vertebræ, Diseases of.*) In shocks and concussions of the spinal marrow, Desault had a high opinion of the benefit resulting from cupping. This was done on, or near the part of the back, which had been struck, and the number of scarifications was proportioned to the strength of the patient. The plan was sometimes repeated the same day, and for several days in succession; and when the patient could not bear the loss of more blood, dry cupping was employed, which, in this country would be deemed less efficacious than stimulating liniments or blisters. In diseases of the spine, Desault also preferred the moxa to caustic issues.

3. *Retention of Urine from Distention of the Bladder.*—Desault thought that this form of the disorder might very properly be called *secondary*, because it is invariably preceded by a *primary* retention. Of course its remote causes are all those circumstances which may bring on the other forms of the complaint; but its immediate cause depends altogether upon the weakness and loss of irritability in the bladder, occasioned by the immoderate distention of its coats. The disorder frequently occurs in persons, who from bashfulness, indolence, or intense occupation, neglect to make water when they first have a desire; or who cannot for a time empty the bladder in consequence of some temporary obstruction in the urethra. Although the impediment to the escape of the urine no longer exists, and the bladder is in other respects sound, yet as this organ has been weakened by the excessive distention of its coats, it cannot now contract sufficiently to obliterate the whole of its cavity, and expel the last portion of urine.

The indication is simple; for there is not here, as in other retentions of urine, another disease to be remedied. The catheter, when left in the bladder, generally proves adequate to the restoration of the tone of this viscus. I do not conceive, however, that English surgeons will place any confidence in warm diuretics, which were commended by Desault, though they may join him in the approval of a tonic plan of treatment in general. When the urine flows from the catheter in a rapid stream, and is projected to some distance, and when it also passes out, between the catheter and the urethra, it is a sign that the bladder has regained its power of contraction, and that it can empty itself without the aid of the instrument. In this circumstance, the catheter is to be discontinued, and the patient may gradually resume his usual mode of life. But when the urine is discharged only in a slow stream, the catheter cannot be laid aside, without the bladder becoming distended again, and losing whatever degree of tone it may have recovered.

The time which the bladder takes to regain its power of contracting, varies considerable in different cases. When the disease is accidental and sudden, it frequently goes off in a few days. When it has come on in a slow manner, it usually lasts about six weeks. However, the cure is not to be despaired of, if the paralytic affection of the bladder should continue much longer. Sabatier says, that he has seen patients wear a catheter upwards of ninety days, and yet ultimately get completely well. When there is reason for believing that the urine will come away of itself, the use of the catheter may be discontinued. When the patient makes water very slowly; when he is obliged to make frequent attempts; and when he feels a sense of weight about the neck of the bladder; this organ has not completely recovered its tone, and the employment of the catheter is still necessary. When the patient could make water tolerably well in the day, but not during the rest of the twenty-four hours, Sabatier often saw benefit arise from the catheter being worn only in the night-time.

When three or four months elapse, without amendment, Sabatier states his conviction, that the tone of the bladder is lost for ever. In this unfortunate case, the patient may continue the flexible catheter, which he should be taught to introduce himself, as often as necessary.—(See *De la Médecine Opératoire*, t. 2.)

Among the means deserving of trial, when the contractile power of the bladder does not return with the use of the catheter, I have to mention the tincture o. cantharides; bark; the sulphate of quinine; steel medicines; blisters applied to the sacrum, and kept open with the savine ointment; and cold washes to the hypogastric region.

In all cases where the incapacity of the bladder to contract, whether from weakness or paralysis, is the cause of retention, and where, though the bladder continues distended, a certain quantity of urine is voided daily, mistakes are particularly liable to be made. Thus besides the chance of the disease being mistaken for an abscess, which, as Colot states, was not uncommon in his time, other errors may take place. Sabatier was consulted about a lady who had been advised to repair to some distant mineral waters, with the view of dispersing a tumour, which remained after a difficult labour, and was supposed to be in the uterus itself. However, the swelling turned out to be only a retention of urine, as it disappeared as soon as the catheter was introduced. Here no suspicion had been entertained of the real nature of the case, because the patient had voided her urine without any apparent difficulty, and in reasonable quantity, for the five or six weeks during which the swelling existed.

In a thesis by Murray, a case is recorded in which the swelling of the bladder was so considerable, that it was mistaken for dropsy. The abdomen of a delicate woman began to enlarge without any particular pain, and the cause was at first supposed to be pregnancy. This idea, however, was removed by the enlargement increasing too rapidly, attended with a great deal of anasarca of the lower extremities, arms, and face. The patient was now considered to be dropsical; and a surgeon was sent for to tap the abdomen. The fluctuation in the belly was quite evident. Fortunately, before the operation was done, a trial of diuretic medicines was determined upon; and while this plan was going on, the patient was attacked with a total retention of urine for three days; a symptom which she had not previously suffered. It was now judged prudent to pass a catheter before the trocar was employed. Eighteen pints of urine were drawn off, and the swelling of the abdomen subsided. The next day twelve more pints of urine were drawn off. The anasarca, which was entirely symptomatic, disappeared. The application of cold water re-established the tone of the bladder, so that when three pints of urine had been drawn off by means of the catheter, the patient herself could spontaneously expel three or four others, with the aid of pressure on the hypogastric region.

The retention of urine caused by weakness or paralysis of the bladder, and the swelling above the pubes, may continue a long while without any inconvenience excepting a sense of weight about the hypogastric region, and frequent inclination to make water. Sabatier has known patients labour under the complaint more than six months.

4. *Retention of Urine from Inflammation of the Bladder.*—According to Desault, writers have ascribed different effects to an inflammation of the neck of the bladder, and to the same affection of the body of this viscus. They have in fact regarded the first case as a cause of retention; and the last as a cause of incontinence of urine. An inflamed, highly sensible bladder, instead of being weakened, has been supposed to acquire an increase of energy, and to contract with greater vigour. But if there had not been retentions of urine, which could be referred to nothing but inflammation of the bladder, still analogy might have undeceived us; for an inflamed muscle is never found disposed to contract, and if it be compelled to act, its action is always feeble.

Plethoric, bilious subjects are said to be particularly liable to this species of retention. It is also frequently occasioned by the abuse of wine, or other spirituous liquors, heating diuretic drinks, or the external or internal employment of cantharides. This form of the

complaint makes its attack suddenly, and may be known by the frequent desire to make water; the acute pain in the region of the bladder; pain, which is increased by the efforts to make water, and which shoots up to the loins and along the urethra to the end of the glans; by the frequency and hardness of the pulse, and other symptoms of fever; by the aggravation of the pain when the hypogastric region is pressed; by the easy passage of a catheter into the bladder; by the acute pain which is excited by the instrument touching the inside of this organ; and by the red, inflammatory colour of the urine.

In this case the most prompt assistance is necessary. The urine, which is a source of additional irritation, should be drawn off. The catheter should be introduced with great gentleness, and merely far enough to let its eye pass beyond the neck of the bladder.

The inflammation itself is to be counteracted by the most powerful antiphlogistic remedies, large and repeated venesections; the application of leeches to the perinæum and hypogastric regions; the warm bath; clysters; fomentations on the abdomen; and cold mucilaginous beverages. When the inflammation extends to the other abdominal viscera, attended with hiccough and vomiting, and continues beyond the sixth day, the patient's life is in extreme danger.

5. *Retention of Urine from Hernia of the Bladder.*—An inability to discharge the urine is a symptom generally attending hernia of the bladder. But the weakness of this organ is not always the sole cause of the infirmity; for the urethra itself makes greater resistance than natural to the issue of the urine. As the neck of the bladder is drawn out of its right position by the portion of this organ which actually protrudes, the beginning of the urethra also undergoes an elongation, and a change of its curvature, by being pressed towards the symphysis of the pubes, and its diameter is likewise diminished. The urine may also be detained in the pouch composing the hernia, in consequence of the communication between this and the rest of the bladder being too small, or indirect, or perhaps from the hernial portion not being compressed by the action of the abdominal muscles, or capable of any contraction itself. However, the rest of this organ, within the pelvis, can itself rarely expel the last drops of the urine. Its complete contraction cannot be accomplished without great difficulty; and, in the end, it almost invariably follows, that the urine is retained both in the protruded and unprotruded portions.

When a retention, arising from a hernia of the bladder, is complete, and occurs in both parts of this organ, there is in addition to the symptoms common to other retentions produced by weakness of the bladder, a more or less considerable swelling in the situation of the hernia. The tumour is unattended with any change of the colour of the skin; is not very tender; and it presents a feeling of fluctuation sometimes obscure, sometimes very distinct. When the swelling is pressed upon, the desire to make water is excited or increased, and occasionally a few drops escape from the urethra. As soon as the urine has been drawn off with a catheter, and the patient is put in a posture in which the protruded portion of the bladder is higher than the rest of this organ within the pelvis, the tumour subsides, and it is some time before it becomes large again.

When the hernia is recent, and the protruded portion of the bladder small and reducible, the part ought to be returned and kept up with a truss. When the part is adherent and irreducible, the swelling ought to be emptied by pressure and supported with a suspensory bandage. If the hernia could in this manner be made to return gradually into the abdominal ring, a truss would afterward be requisite. Proposals have been made to endeavour to excite adhesive inflammation in the cavity of the protruded part of the bladder by compression gradually increased, and thus obliterate the pouch in which the urine lodges. Although Desault thought the attempt cautiously made justifiable, he deemed the result very uncertain.

Were the retention of urine accompanied with a strangulated state of the protruded bladder, and the contents could not be pressed into the other part of this organ, a puncture of the swelling with a trocar has been advised. But if there were an enterocele also present, as often happens, this operation would be attended with risk of injuring the intestine. Hence, Desault preferred opening the tumour by a careful incision, and he even approved of cutting away the protruded cyst, if the communication between it and the rest of the bladder were obliterated.

6. *Retention of Urine caused by displacement of the Viscera of the Pelvis.*—The displacements here signified are, a retroversion, prolapsus, and inversion of the uterus, and a prolapsus of the vagina or rectum. When the intimate connexions of the bladder with the uterus and vagina in the female, and with the rectum in the male subject are considered, it is obvious that the latter parts cannot be displaced, without drawing along with them the bladder; and that, in this state, whatever may be its contractile power, it cannot contract so perfectly as to expel the whole of the urine. To this deficient action of the bladder is necessarily joined an increase of resistance on the part of the urethra; for the beginning of this canal being drawn by the bladder, changes its accustomed direction, and such alteration cannot be made without the sides of the tube being pressed together. Thus the retroverted uterus draws the os tincæ above the pubes, and the posterior part of the bladder is displaced, which, in its turn, draws along with it the commencement of the urethra, pulls it upwards, and increases the curvature which this canal describes under the symphysis of the pubes, against which it is forcibly applied.

In a prolapsus or inversion of the womb, vagina, and rectum, the back part of the bladder, instead of being drawn upwards and forwards, is pulled downwards and backwards, and the curvature of the urethra is totally altered. Below the pubes, the bladder forms a convexity, and not a large concavity, as in the instance of a retroversion of the womb. This position of the parts should always be recollected in passing the catheter, as it shows what curvature and direction should be given to the instrument, in order to facilitate its introduction.

These retentions of urine are not often followed by any very bad consequences. It is generally sufficient to rectify the wrong position of the bladder, and the commencement of the urethra, by the reduction of the displaced viscera; and a cure is then a matter of course, unless the excessive distention should have induced considerable weakness of the bladder, in which event, recourse must be had to the means previously recommended for this state of the organ. The reduction of the viscera generally forms the first indication, and the manner of accomplishing it is described under the head of *Uterus*. When the reduction is not immediately practicable, or when it fails to remove at once the retention of urine, the catheter is to be used. Frequently, when the urine has been drawn off, the reduction becomes more easy; but sometimes the altered direction of the urethra renders the introduction of the catheter difficult; nor will the instrument pass, unless it be accommodated to the preternatural state of that canal. Thus, in the retroversion of the uterus, a catheter, very much curved, answers better than one nearly straight, like that commonly used for females.

A curved catheter, says Desault, only answers in cases of prolapsus uteri, &c.; but with this difference, that in a retroversion, the concavity of the instrument must be turned towards the pubes, but in the prolapsus, towards the anus. Sometimes, the catheter will not pass unless it be rotated, as it were; and sometimes when a silver catheter cannot in any manner be introduced, an elastic one will readily enter.

Were every effort to reduce the viscera and pass a catheter unavailing, and the hazard of the bladder giving way urgent, the surgeon would be called upon to let out the urine with a trocar.—(See *Bladder, Puncture of.*)

7. *Retention of Urine from the pressure of the Uterus or Vagina on the Neck of the Bladder.*—Besides the distention of the uterus and vagina in pregnancy and parturition (which cases I mean to pass over as belonging more properly to midwifery), there are other conditions of these organs which may give rise to a retention of urine. Thus it sometimes arises from the presence of various kinds of tumours or collections of blood, or other fluid in the uterus or ovary; or the distention of the vagina with the menses, pessaries, &c.

In such cases, the retention of urine being only symptomatic, the prognosis must depend upon the nature of the cause, of which the interruption of the urinary evacuation is only an effect. The latter complaint is here not very dangerous, because its inconvenience may be obviated by means of the catheter. But when

the cause of the retention of urine is easily removed, and the tone of the bladder is not impaired, even the catheter is not always necessary, as when the complaint is induced by a pessary or collection of blood in the vagina. In other examples, in which the cause of the difficulty of making water cannot be immediately obviated, as in cases of tumours, the catheter must be employed. In scirrhous and cancerous diseases of the uterus also, this instrument is the only means of relieving the retention of urine, as nature and art can do little for the removal of the cause. It ought to be known, however, that as these last diseases increase, an incontinence often succeeds to a retention of urine, in consequence of ulceration taking place between the upper surface of the vagina and the lower part of the bladder.

8. *Retention of Urine from Pressure of the Rectum upon the Neck of the Bladder.*—Abscesses in the vicinity of this intestine; hemorrhoidal tumours; alvine concretions; and the scirrho-contracted state of the gut, &c., may bring on a retention of the urine by pressure on the neck of the bladder. The irritation also, existing in these cases, may tend to produce the complaint by exciting a spasmodic contraction of the adjacent part of the urethra. Here the relief of the retention of urine is to be effected by removing or curing the other disorder which operates as its cause. If this cannot be immediately accomplished, the catheter must be used, though, in several instances, it will be better to avoid even the irritation of the catheter, and try the effects of bleeding, the warm bath, and opium, which will frequently enable the patient to make water. The last means, however, will not suffice, when the cause of the retention is likely to continue a long time.

9. *Retention of Urine from foreign Bodies in the Bladder.*—Without stopping to consider the uncommon kinds of retention produced by carcinoma, fungous diseases, and hydatids in the bladder, let us pass on to the case in which the urine is obstructed by a calculus at the neck of the bladder. Here the patient, by altering his position, frequently changes the situation of the stone, and is immediately able to make water again. However, this expedient will only procure relief while the calculus is loose in the cavity of the bladder; for, after it has become fixed in the commencement of the urethra, it must either be pushed back with a catheter, taken hold of and brought out with the urethra-forceps used by Sir A. Cooper, broken or pulverized by lithotritic instruments, or extracted by a kind of operation, resembling the apparatus minor.—(See *Lithotomy.*)

Many instances of various kinds of worms in the bladder are upon record. On this subject, an interesting paper was published a few years ago by my friend Mr. Lawrence, who met with an example, in which an undescribed species of worms was abundantly voided from the bladder. "The origin of those animals (says Mr. Lawrence) which inhabit the internal parts of living bodies, is involved in much obscurity. Although the intestinal worms appear manifestly, from their peculiar form, consistence, and organs, to be particularly designed for those situations in which they are found; although they have generative organs, and no similar animals are known to exist out of living bodies, yet it has been generally conceived, that the germs from which they spring enter from the mouth. The production of hydatids in various parts of the body, cannot, however, be accounted for on such a supposition; neither can we very easily conceive that ova should enter from without into the urinary organs." The following facts, also stated by Goeze (as Mr. Lawrence observes), entirely overturn this opinion. Professor Brendel, of Göttingen, found ascarides in the rectum of an immature embryo. Blumenbach discovered tæniæ in the intestinal canal of young dogs a few hours after birth, &c.—(*Versuch einer Naturgeschichte der Eingeweidewürmer*, p. 55.) The case which Mr. Lawrence has recorded, exhibits an unquestionable instance of peculiar and undescribed worms, voided from the urinary passages. This gentleman says, that he knows of no other case in which a distinct species of worm has been clearly proved to come from the bladder. Most of the cases published were instances of common intestinal round worms, which sometimes perforate the intestines and are discharged by abscesses, or get into the bladder after the formation of adhesions between this organ and the bowels. In other instances, coagula of blood, mucus, or portions of the mucous coat of the bladder, have been mistaken for worms; and as Mr. Lawrence farther observes, some of the descriptions can apply only to larvæ of insects. Two specimens of this last sort, he has seen himself, which were sent from the country as worms voided from the bladder.—(See *Medico-Chir. Trans. vol. 2, p. 382, &c.*)

In whatever way these animals get into the bladder, a retention of urine may be produced, either when they are numerous, or when there is only one present, but large enough to obstruct the vesical orifice of the urethra. In the very curious example related by Mr. Lawrence, the passage of the urine was obstructed, and the use of the catheter continually necessary. The oil of turpentine was given internally, with some appearance of benefit at first; but it afterward brought on febrile symptoms and erysipelas, and its exhibition could not be kept up. It was then injected into the bladder with an equal part of water. This rather accelerated the discharge of the worms; but they came away at times, whether the injection was used or not; and as this means produced the erysipelatous indisposition again, it was left off. Olive oil was afterward injected: the irritation after it was less, and the fits of pain about the bladder less violent. It was calculated at the time when Mr. Lawrence was writing the particulars of the case, that from 800 to 1000 worms had been discharged. For a detail of the symptoms, and a particular description of the worms themselves, I must refer to the above-mentioned publication.

According to the observations of Desault, a retention of urine is frequently occasioned by coagula of blood in the bladder. The blood is said sometimes to come from the kidneys, sometimes from the bladder, and sometimes it even regurgitates from the urethra. While fluid, it may be expelled with the urine; but when coagulated, it is no longer capable of being discharged. It is the blood which passes into the bladder after wounds, or the operation of lithotomy, that is most disposed to coagulate. If the clots were too large to pass through a catheter, the best plan would be to inject into the bladder lukewarm water, for the purpose of loosening and dissolving them. An instance of retention of urine from a large quantity of coagulated blood in the bladder is related in the 2d vol. of the Medical Gazette, p. 255. The injection of warm water, and the use of a very long catheter, succeeded in procuring the discharge of the urine.

A retention of urine has sometimes arisen from the entrance of a piece of bougie into the bladder. Even whole bougies, which had not been properly secured, have been known to glide into the cavity of that organ. As Desault observes, the urethra appears to possess a kind of antiperistaltic action, by which it tends to draw into the bladder whatever substances it includes; for, says he, it is constantly noticed, that when these substances are once within the urethra, if they be not expelled by the urine, they always advance towards the bladder; a circumstance which cannot be accounted for by their weight.

The insinuation of foreign bodies into the bladder is a serious occurrence both for the patient and surgeon. The former cannot avoid the consequence, which will sooner or later originate from the extraneous substance, except by submitting to a dangerous and painful operation; the latter will be accused of being the author of all the evil, and will find it difficult to exculpate himself. In order to obviate the necessity of cutting into the bladder in such cases, Desault proposed the use of small spring-forceps passed into the bladder through a cannula; but, although the instrument seemed to answer on the dead subject, no instances of its doing so on living patients are on record. Were any instrument likely to succeed, I think it would be the urethra-forceps, shaped like a sound, employed by Sir A. Cooper for the extraction of small calculi from the bladder, or the forceps used in lithotrity.—(See *Lithontriptor*, *Lithotomy*, and *Urinary Calculi.*)

10. *Retention of Urine from Inflammation of the Urethra.*—In order to comprehend the mechanism of this case, it is necessary to remember that inflammation never exists without swelling, and that every tumefaction of the lining of the urethra must necessarily lessen its diameter. Inflammation of the urethra is most commonly produced by the external application

or internal exhibition, of lyttæ, by gonorrhœa, the unskilful use of the catheter, the employment of stimulating injections, bougies, &c. Together with the lessening of the canal by the effect of swelling, there can also be no doubt, that in many of these instances a spasmodic contraction of the urethra and neck of the bladder also contributes to the retention of urine. Although Desault believed, that inflamed parts, endued with a contractile power, were not disposed to contract in that state, yet it should be recollected, that, even admitting this to be true, the whole length of the urethra is seldom inflamed, and a part of it may therefore be affected with a spasmodic action, without the theory espoused by Desault being at all implicated. The effects of opium, tobacco, and other antispasmodics often evinced in immediately relieving these kinds of retention of urine, seem indeed to leave no doubt respecting the existence of more or less spasm in the passage. Whatever may be the cause of inflammation of the urethra, the diagnosis is free from all obscurity. Besides the general symptoms of inflammation, the patient complains of a scalding sensation in the passage; he experiences a great deal of smarting, which is sometimes insupportable when he makes water; the penis becomes in some degree swollen, and more tender; and a very little pressure on the urethra gives acute pain. In the mean time, the stream of urine becomes lessened; and at length this fluid can only be voided in a very narrow current, or only by drops, and often not at all.

The disorder is to be treated on antiphlogistic principles. Diluting, cooling, mucilaginous beverages, venesection, leeches to the perinæum, the warm bath, opium, particularly in the form of clysters, and fomentations, are the means which usually give relief. When inflammation exists in the urethra, it is always desirable to avoid as long as possible the employment of catheters, which create irritation, and of course increase the cause of the retention. It is particularly in cases of this description, and in the retentions of urine arising from strictures, that Mr. Earle has suggested the use of tobacco in the form of clysters; a method deserving adoption when the means above enumerated are unavailing, and it is preferable to the catheter, because it does not cause any increase of irritation and inflammation in the urethra.—(See *Med. Chir. Trans. vol.* 6, *p.* 82, *&c.*)

11. *Retention of Urine from Laceration of the Urethra.*—The urethra is sometimes, ruptured by violent contusions on the perinæum, and the rough and unskilful use of bougies and catheters. The consequences usually are an extravasation of urine in the cellular membrane of the scrotum and penis, a considerable dark-coloured swelling of these parts often followed by sloughing, and retention of urine. The treatment consists in introducing an elastic gum catheter into the bladder with as little delay as possible, and keeping it there until the breach in the canal is repaired. At the same time, the evils threatened by the effusion of the urine are to be averted as much as possible, by making two or three free incisions in a depending part of the swelling, and the employment of fomentations and antiphlogistic remedies.

12. *Retention of Urine from Tumours situated in the Perinæum, Scrotum, or Penis.*—A retention of urine has been known to arise from phlegmonous swellings and abscesses, extravasations of blood, and urinary tumours and calculi formed in the perinæum and scrotum; also from the pressure of a sarcocele, hydrocele, a very large scrotal hernia, an aneurism of the corpus cavernosum, a ligature on the penis, &c.

The radical cure of all such retentions of urine can only be accomplished by curing the disease on which they are dependent. However, until the cause can be obviated, the urine must be drawn off with a catheter. Elastic gum catheters usually enter more easily than those made of silver, as by their flexibility they accommodate themselves better to any deviation of the urethra from its ordinary direction. Desault particularly recommended a catheter of middling size to be selected, and introduced armed with its stilet until it stops in the canal; when he advised withdrawing the stilet for about an inch, in order to leave the beak of the instrument quite free, so that it might follow the curve of the urethra. Then the tube and the stilet were pushed farther into the canal, care being taken, however, to keep the stilet drawn back some distance from the extremity of the instrument. By these precautions, says Desault, the catheter may always be got into the bladder. Should the introduction prove neither painful nor difficult, Desault thought it better not to annoy the patient by making him continually wear the instrument.

13. *Retention of Urine from Disease of the Prostate Gland.*—When the swelling of the prostate gland is of an inflammatory kind, the retention of urine makes its appearance with the same kind of symptoms as attend inflammation about the neck of the bladder.

Here similar treatment to that commonly adopted for the retention of urine produced in the latter case is indicated; particularly bleeding, fomentations, the warm bath, opening medicines, anodyne clysters, the tinctura ferri muriati, and, in very obstinate urgent cases, an enema of tobacco. If these means fail, the surgeon may gently endeavour to introduce an elastic gum catheter.

The symptoms of the retention of urine, caused by chronic enlargement of the prostate gland, and the reason of the impediment to the discharge of that fluid in such a case, are explained in another part of this work.—(See *Prostate Gland.*) From the remarks there introduced, it appears, that when the regular evacuation of the urine begins to be impeded, the catheter becomes indispensable, though the surgeon will often be foiled in his endeavour to draw off the urine with it, unless he be duly acquainted with the morbid changes produced in the parts. And, as Sabatier long ago very correctly observed, the urine may not be discharged, though the instrument enter a considerable way, either because its beak becomes entangled in the prostate gland, or *between a swollen portion of this gland and the neck of the bladder*, and does not reach the urine. Hence, he recommended the employment of a catheter with a very long beak, which should also be bent considerably upwards. When, however, all efforts to pass a catheter fail, the only resources are to force a passage with a conical catheter, or to puncture the bladder above the pubes. I believe that the latter proceeding is scarcely ever necessary in this particular form of retention of urine, as, with moderate skill, an instrument may almost always be passed by the urethra. Such is also the opinion of Sir Astley Cooper.—(See *Catheter*, and *Bladder, Puncture of.*)

14. *Of the Retention of Urine produced by Strictures in the Urethra.*—From the account which is given of strictures in another part of this Dictionary (see *Urethra, Strictures of*), it appears that almost every stricture, bad as it may be, is capable of being rendered still worse, and the morbid part of the urethra more impervious, by a spasmodic affection. Going out of a warm into a cold situation, drinking, and other kinds of intemperance, will often bring on an irritable state of the canal, attended with a spasmodic action of the strictured part, an increased difficulty of voiding the urine, and even a total retention of this fluid. The patient makes repeated efforts to relieve himself, but hardly a drop of urine is discharged. In the mean while, the bladder becomes filled, and ascends above the pubes, the abdomen grows tense and painful, fever comes on, the countenance looks red, the brain becomes affected, and circumstances assume an extremely urgent appearance.

In this case antiphlogistic means should be adopted without delay. The patient ought to be bled, if nothing in his constitution and age prohibit this evacuation, which it may even be proper to repeat. He should also be put into the warm bath, and fomentations should be continually applied to the hypogastric region. Slightly diuretic beverages may be prescribed, and leeches put on the perinæum. The principal means, however, from which the greatest benefit may be expected, is a liberal dose of the tinctura opii, together with an anodyne clyster. This is also another example for which Mr. Earle has particularly recommended the exhibition of tobacco in the form of a clyster, and he has related a case in illustration of the efficacy of the plan.—(See *Medico-Chir. Trans. vol.* 6, *p.* 88.) The tinctura ferri muriati, which, according to Mr. Cline, has a specific effect in overcoming spasm of the urethra, seems also worthy of trial. Indeed, it should always be tried before tobacco, which, being sometimes violent in its effects, ought perhaps to be the last resource in the way of medicines. When such measures fail in enabling the patient to empty his

bladder, and this viscus is becoming more and more distended, an immediate attempt should be made to introduce a small flexible elastic gum catheter through the stricture or strictures into the bladder, which object may be frequently accomplished, when due care, perseverance, and gentleness are not neglected.

Sometimes, when a small flexible catheter cannot be introduced, a fine bougie admits of being passed into the bladder, and, on being withdrawn, the urine follows, and is discharged.

When all the preceding plans prove unavailing, and the danger arising from the retention of urine continues to increase, either the stricture must be perforated with a stilet made for the purpose, forced with the conical sound (see *Catheter*), an incision practised behind the obstruction, or the bladder punctured. The cannula of the trocar should then be left in the wound till the strictures are either cured, or, at least, till the urine resumes its natural course.

15. *Retention of Urine from the Lodgement of foreign Bodies in the Urethra.*—That such accident must obstruct the discharge of urine, is too plain to need any particular explanation. Calculi are the most common substances which bring on this kind of case, but articles introduced into the urethra from without, such as bougies, large pins, &c., are occasionally lodged in the passage; and I once extracted from a man's urethra a long black pin, with which he had been examining the passage. The head of it was towards the perinæum, and the point about two inches from the orifice of the glans. I passed the point through the lower surface of the urethra, and then taking hold of it, drew it farther out, turned the head towards the glans, from the orifice of which it was then easily removed. When substances like calculi lodge, oily injections are sometimes tried, with the view of rendering the passage more slippery, and occasionally the dilatation of the canal with bougies and catheters, followed by a very forcible expulsion of the urine, has answered. The ancients sometimes tried the effect of suction. When the foreign body is closely embraced by the urethra, and it cannot be pushed forwards by the fingers, Desault recommends endeavouring to extract it with the forceps invented for the purpose by Mr. Hunter, and which are contained in a cannula; or the urethra-forceps spoken of in the articles *Lithotomy* and *Urinary Calculi* might be employed. When, however, the foreign body is too large to be taken out in this manner, it must be extracted by an incision. If an elastic catheter be now kept in the urethra, so as to prevent the urine from coming into contact with the cut part, the wound will heal very well. Some time ago there was published a case of calculus in the urethra, attended with dysury, where almost instantaneous relief was obtained from the exhibition of a tobacco clyster. The patient soon felt a strong desire to void his urine, and "upon making the attempt, a large calculus came rolling along the urethra, with complete relief of all his complaints."—(See *Edinb. Med. and Surgical Journal, vol.* 12, *p.* 373.)

UTERUS, INVERSION OF. This case may either be complete or incomplete. When it is incomplete, only the fundus of the uterus passes through the os tincæ. When the inversion is complete, the uterus becomes entirely turned inside out, passing through the opening in its cervix, dragging along with it a part of the vagina, and descending more or less far down, sometimes even between the patient's thighs.

The inversion of the uterus mostly arises from the manner in which the placenta is extracted after delivery. Immediately after parturition the uterus is not yet contracted, and its cervix is in a widened state. When things are thus disposed, the uterus may easily follow the after-birth, which is attached to it, and thus become inverted. The event is particularly liable to happen; 1st, When a premature attempt is made to extract the placenta. 2dly, When the funis is pulled outwards, without due care being taken to support the uterus with the fingers of the left hand. 3dly, When the operator draws out the after-birth too roughly and violently. Though the placenta is sometimes so adherent that its extraction is difficult, and a risk must be encountered of dragging down the uterus with it, this disagreeable accident may generally be avoided by performing the necessary separation of the parts with the fingers introduced into the cavity of the uterus.

The inversion following delivery does not always proceed from unskilfulness; but sometimes happens, notwithstanding every precaution, either because the patients themselves make too violent efforts, or because the uterus is enlarged and heavy; or else in consequence of some predisposition, some unusual laxity of the organ, which can neither be foreseen nor prevented. Ruysch saw an inversion of the uterus take place after the expulsion of the placenta, although delivery had occurred in the most favourable way.

Mr. Windsor believes that when the uterus and vagina are in a relaxed state, and the female has been subject to prolapsus uteri, there is a greater disposition to the occurrence of inversion at the time of labour than when such condition of the parts does not exist.—(*Med. Chir. Trans. vol.* 10, *p.* 360.)

A tendency to the accident is very common in women who have once been afflicted with it. Amand mentions a woman who had an inversion of the uterus after her first delivery, but the part was reduced. She was attended by Amand again in her next confinement, and another inversion of uterus, quite as bad as the first, would have happened, had he not, on perceiving the disposition to the accident, introduced his finger into the cavity of the uterus, and separated the placenta from its attachments, before making any attempt to extract it.

Besides causes connected with parturition, there are others of a different nature. Ruysch, Mauriceau, and Lamotte supposed an inversion of the uterus could only happen at the time when the placenta was extracted, or a little while afterward. The accident seemed to them impossible at any other period, both on account of the thickness of the uterus, and the smallness of the os tincæ. However, many facts prove that the case may also depend on internal causes, and affect women who have never had children as well as others who have had them. Thus, polypi of the uterus may bring on inversion of the part. As their pedicle is attached to the fundus of the uterus, they may easily drag it downwards when its texture is lax and soft, particularly as the operation of their weight is continual.—(See *Denman's Plates of a Polypus, with an Inversion of the Uterus, fol.* 1801.) Uterine hemorrhages may also be conducive to the accident, both because they relax the texture of the uterus, and because they are usually attended with acute pain, which makes the diaphragm and abdominal muscles act upon the uterus with all their power.

Levret speaks of a case of inversion of the uterus, where the displacement was not noticed until five years after delivery. In this example, it is conjectured that the very gradual and slow formation of the disease must have been the reason of its not having attracted earlier attention.—(*Dict. des Sciences Méd. t.* 23, *p.* 288. Also, *Baudelocque, in Brogniard, Bulletin des Sciences*, 2, *n.* 1.)

When an inversion of the uterus takes place after delivery, there are certain symptoms by which it may easily be known. The uterus, in its natural situation, thickened and swelled as it is at this period, presents itself in the hypogastric region in the form of a round circumscribed tumour; but when it has fallen downwards and become inverted, a vacancy is felt in the situation which it ought to occupy. When the inver

sion is incomplete, an examination with the fingers detects in the vagina a tumour shaped like the segment of a sphere, having a smooth surface, and surrounded by the cervix uteri as by a kind of collar, round which the finger may easily be passed, either between it and the uterus, or between it and the vagina. When the inversion is complete, which case is more rare than the preceding, a tumour may be felt in the vagina, from which it sometimes even protrudes, apt to bleed, of an irregularly round shape, hanging by a neck, the lower part of which is surrounded by the above circular, thick, fleshy substance, consisting of the os uteri itself. The slightest touch makes the swelling bleed. The part has a red colour, which, however, generally diminishes in proportion to the duration of the displacement. In time, indeed, its surface becomes less sensible to external impressions, and only bleeds at the menstrual periods; the blood oozing from every point of the swelling, and not issuing from a single aperture at the lower part of the tumour, as in cases of prolapsus uteri.

In the incomplete inversion, patients feel acute pain in the groins and kidneys, an oppressive sense of heaviness in the hypogastric region, and a tenesmus; which, compelling them to make violent efforts, forces the uterus farther down, and sometimes produces a total inversion of it. Besides these symptoms, more or less copious hemorrhages also occur. When the inversion is complete, the pain is more acute, the loss of blood more considerable, and the patient often affected with peculiar weakness, followed by cold sweats, convulsions, and delirium.

In both forms of the disease, if the reduction be not almost immediately effected, fatal consequences frequently ensue, either very soon after the accident, from the violence of the hemorrhage, or at a more or less remote period, partly from repeated losses of blood, and partly from the constitutional irritation and disturbance incessantly kept up.

Happily, as Mr. Windsor observes, the accident admits of remedy, if an intelligent person be present to replace the uterus; for, if this be done immediately, and the hand of the accoucheur be retained in the cavity of this organ until it has contracted, and the patient be afterward confined to the recumbent posture, she will generally do well. An unsettled point appears to be, whether the placenta, if still remaining, should be extracted before or after the reduction. Mr. Windsor, who appears inclined to prefer the latter method, refers to two examples, in which each plan was followed by a recovery.—(See *Med. Chir. Trans. vol.* 10, *p.* 360.)

And in all cases, as the same author remarks, the accoucheur, after the expulsion of the placenta, should assure himself by manual examination that the os internum is free, while an endeavour is made to feel the uterus with the hand placed upon the abdomen. "In consequence of the neglect of this practice," says Mr. Windsor, "it is to be feared that many lives have been lost; the true cause of the succeeding hemorrhage not being ascertained till too late, as happened in the fatal case that occurred to a midwife here (Manchester) last winter." Some women perish at once, or within a few hours; and when they live longer, the reduction is exceedingly difficult, because the uterus and its cervix are becoming more and more contracted.

In the reduction, Sabatier regards the interposition of linen between the hands and the uterus as unnecessary, and even disadvantageous; because it prevents the practitioner from having the assistance of a correct feel of the part. The trial should be continued as long as the patient's strength will allow. However, if the tumour were in an inflamed state, it would be prudent to put the patient in the warm bath, use emollient applications, and exhibit anodyne and laxative medicines, &c.

When the reduction cannot be accomplished, many patients die; while others survive, subject to an oppressive sense of weight and frequent hemorrhages, which bring on great emaciation. Sabatier attended two patients who had had an inversion of the uterus six months, and yet they were able to go about their family affairs. The same author had heard of other women who had been afflicted with an inversion of the uterus several years.

If the reduction cannot be performed, and the patient survive the immediate effects of the injury, "some degree of inflammatory symptoms, accompanied with fever, ensues. The abdomen becomes full, tender to the touch, and, at its lower part, sometimes rather hard. There is costiveness of the bowels, and sometimes retention of urine, requiring for a time the use of the catheter. By the use of fomentations, enemata, laxatives, and an antiphlogistic regimen, the symptoms abate, the power of expelling the urine, especially if the uterus is first raised a little in the vagina, is regained, and the patient gradually recovers the full power of this function. Afterward, she becomes able to walk about, suckles her infant, and perhaps enjoys apparently even a tolerable state of health; yet the sanguineous discharges generally after a time return profusely, and her pale countenance and emaciated appearance indicate the greatest debility.

About the time when she relinquishes the office of suckling, the menses return more regularly, the discharges of blood are very considerable in quantity, or of long duration, the mucous discharges are generally copious at other times, and the constitution begins to sink under the reiterated losses it sustains. The pulse becomes frequent, the appetite is impaired, a cough, with hectic symptoms, sometimes occurs, and the patient is quite unable to pursue her usual domestic duties. In this state, palliative means, as the use of astringent and other remedies, become inadequate to check the exhausted progress of the complaint, and the unfortunate sufferer must soon perish unless some decisive means be devised for her relief. In this painful extremity, the extirpation of the uterus itself has been proposed as the most efficient means of relief; and, formidable as the operation at first view seems, it is known to have been already performed with success."—(*Windsor, in Med. Chir. Trans. vol.* 10, *p.* 361—363.)

One of the most afflicting consequences of an inversion of the uterus is so considerable an inflammation of the part, as to induce a danger of its mortifying. In this circumstance, the extirpation of the uterus has been also suggested, and even practised; an operation that has had but little success, the majority of patients on whom it has been practised under such circumstances having died.

The practice of extirpating the inverted uterus through apprehension of the part mortifying, cannot be too strongly reprobated; for, unless mortification has really happened, the uterus may possibly be brought into a state again in which the inconveniences arising from its inversion would be very supportable, and the operation altogether avoided. Even supposing mortification were to take place, the indication would be to appease the bad symptoms, and promote the separation of the sloughs by suitable applications, without doing any injury to the living parts. One example, in which the latter practice was successfully adopted, is recorded by Rousset. That the extirpation of the uterus, when this organ is completely or incompletely inverted, totally irreducible, and attended with the sufferings and reduced health so well described by Mr. Windsor, may sometimes be advisable, cannot now be doubted. The unequivocal examples on record of the removal of the cancerous uterus by Osiander, Dupuytren, Langenbeck, and others, and the cases published by Mr Newnham, Mr. Windsor, and Dr. C. Johnson (*Dublin Hospital Reports, vol.* 3), where the inverted and irreducible uterus was successfully extirpated, furnish sufficient evidence in favour of the practice, without referring to numerous other cases reported on older authorities, the correctness of some of which may be questionable.

In fact, polypi, growing from the uterus, frequently attain so considerable a size, that they protrude out of the vagina, and are occasionally mistaken for the uterus itself. The surgeon extirpates the tumour with a ligature; the operation does not undeceive him about the nature of the part; his patient has a favourable recovery; and the case is published as an instance of the successful extirpation of the uterus itself.

Although it is easy to distinguish the inversion of the uterus which happens soon after delivery, it is not so to make out the nature of such cases as happen in other circumstances, notwithstanding the presence of the same kind of symptoms. As cases of the latter kind are uncommon, and, consequently, not expected

mistakes are the more liable to be made. A polypus has often been mistaken for an inversion of the uterus; but it should be recollected, that the upper part of a polypus is always narrow, and the tumour, which is not very sensible, is irreducible; whereas, the uterus, in a state of incomplete inversion, forms a semispherical swelling, sometimes a little oblong, but always broader above than below. It is very sensible, and may generally be reduced. And when the inversion is complete, the tumour has a greater resemblance to a polypus, inasmuch as it seems to have a pedicle, but, the impossibility of introducing a probe far at the circumference of such pedicle, as can be done in cases of polypi, will generally serve at once as a criterion of the nature of the disease.

The greatest obscurity in the diagnosis is said to prevail when the inversion is partial and chronic, because the os uteri then encircles the summit of the tumour, just as it does a polypus, and, in both cases, the finger will pass all around between the parts.—(See *Newnham's Essay on Inversio Uteri, with a History of the successful Extirpation of that Organ*, p. 82, 8vo. *Lond.* 1818.) However, as I do not believe, with this gentleman, that the neck of a polypus is frequently as large, and sometimes larger than its inferior portion, I should yet expect, that the difference in the form of the two swellings perceptible on manual examination would here be an important criterion. In general, also, the fact, that inversion of the uterus first happens at or soon after delivery, is a consideration that would tend to a right discrimination of the cases, inasmuch as the first protrusion of a polypus directly after delivery is rare, and when it does happen under these circumstances, is probably always complete, and not partial.

Reduction is the only plan, whether the case has arisen from the weight of a polypus, or from uterine hemorrhage. However, this proceeding is generally useless, when the disease originates from obesity. In the latter case, as the cause still continues in full force, the uterus is soon displaced again, and a pessary is the only means to which the patient can resort.

Having delivered many additional observations on the subject of inversion of the womb, in the second vol. of the *First Lines of Surgery*, ed. 4, I shall here conclude with referring to some works, in which the reader will find valuable instruction on the subject. *F. UTERUS, POLYPI OF. (See *Polypus.*)

UTERUS, PROLAPSUS OF. The womb, situated in the upper and middle part of the pelvis, is but imperfectly secured in its natural place by means of its broad and round ligaments: hence, it sometimes descends into the lesser cavity of the pelvis, so as to pass more or less down the vagina, or even protrude beyond the labia. The first case is the *incomplete*; the second, the *complete* prolapsus uteri.

In the first form of the disease, where the uterus has not passed down so low as to protrude externally, some of the complaints which the patient experiences depend upon the pressure of the displaced viscus upon the parts unaccustomed to it, particularly the bladder and rectum; while other inconveniences arise from the tension of the ligaments, destined to retain the organ in its natural position. These last grievances are chiefly a sense of heaviness in the pelvis, and a dragging pain in the loins; symptoms which are aggravated when the patient sits up, or walks about, but diminish when she remains in bed, though, as the disease when neglected scarcely ever fails to grow worse, they rarely subside altogether. However, such amendment actually sometimes happens, in consequence of the parts becoming gradually habituated to their change of situation. When the disease comes on with great suddenness, the symptoms are remarked to be much more severe than when it takes place slowly: in the first case, long-continued syncope, pain over the whole abdomen, tenesmus, uterine hemorrhage, inflammation of the peritoneum, and severe febrile symptoms may be excited.

With regard to the effects, caused by the pressure of the tumour on the bladder and rectum, they consist of more or less difficulty in voiding the urine and feces. The dysury and constipation increase in proportion as the patient continues in an upright posture, and the uterus descends nearer to the inferior orifice of the vagina. Sometimes the irritation brings on a considerable mucous discharge, which, when the patient suffers little other inconvenience from the prolapsus, is apt to be mistaken for fluor albus or gonorrhœa.

A woman may become pregnant, notwithstanding an incomplete prolapsus of the womb. The displacement may even take place at a more or less advanced period of gestation (*Portal des Accouchemens*), while, in other still more uncommon instances, the prolapsus has been remarked to disappear, when the period of labour drew near. Cases exemplifying both these facts, are related by Loder (*Journ. für die Chir. b.* 2, *p.* 13), by Saviard, Portal (*Mém. de l'Acad. de Chir. t.* 3.), in the Journ. de Médecine, t. 45, and by Chopart (*Traité des Maladies des Voies Urinaires*). A prolapsus uteri may also happen during parturition. —(*Garin, Jour. de Méd. continué, t.* 4, *p.* 265; *Ducreux, Mém. de l'Acad. de Chir. t.* 8, *p.* 393.)

When, in the course of time, a prolapsus uteri changes from the incomplete to the complete state, all the inconveniences depending upon the pressure of the part upon the rectum and bladder, subside; that is to say, the feces and urine are now freely voided. But, on the other hand, the symptoms arising from the stretching of the peritoneum become considerably worse. The uterus drags down with it the vagina, which becomes doubled on itself; and a part of the bladder, connected with the upper part of the latter tube, is also drawn down. Some of the abdominal viscera may even fall into the cul-de-sac, formed by the vagina, and considerably increase the size of the tumour. The swelling, protruding between the thighs, is of an oblong, nearly cylindrical form, and terminates below in a narrow extremity, in which a transverse opening, the os tincæ, may be discerned, from which the menses are discharged at the periods prescribed by nature. However, the cylindrical shape of the tumour may lead to mistakes, for the vagina, being doubled on itself, and exposed to the effects of the air, sometimes looks like skin. Hence, women thus afflicted have occasionally been supposed to be hermaphrodites, the tumour being mistaken for a penis. Such a case is recorded by Saviard.

The patient is generally troubled with tenesmus, and sometimes feels acute pain in the tumour itself, which is subject to inflame and ulcerate, in consequence of its depending posture, the friction to which it is exposed, and the irritation of the urine.

The direction both of the bladder and urethra becomes horizontal, so that the urine is thrown forwards, or even upwards, in which latter case it wets the abdomen. Frequently the bladder cannot be emptied without the assistance of the catheter; and sometimes the displaced uterus becomes affected with inflammation and swelling. In many cases there are profuse hemorrhages. However, some women become so habituated to the disease, that they hardly seem to experience any annoyance from it: whenever they are in an erect posture, and walk about, the womb falls down, bringing with it the vagina; and as soon as they lie down on their backs, the parts as readily return into their natural position again.

The incomplete prolapsus is alone subject to any obscurity, which, however, may be dispelled by manual examination. In this, however, some precautions are necessary. For instance, as the womb generally returns into its natural situation when the patient lies down, the examination should always be made as she is standing up. For the same reason, if she is in the habit of lying long in bed, the morning is not the best period of the day for the examination. The practitioner may also be deceived, if he examine the parts when the rectum and bladder are distended with their

contents, in which state the uterus may be hindered from descending as low as at other periods.

If attention be paid to these circumstances, an incomplete prolapsus may always be distinguished without risk of error. However, the records of surgery prove, that the case has sometimes been mistaken by the inexperienced or ignorant for a polypus, and the part extirpated under this supposition. So serious a blunder will be avoided, if care be taken to remember, that polypi are generally softer, and less sensible, than the uterus; that, in a case of prolapsus, the os tincæ is situated at the lower part of the swelling; and that if by chance any resembling aperture should be met with upon the corresponding portion of a polypus, the prolapsus may still be known by the greater depth to which a probe will enter such opening. A polypus of the uterus, I believe, is always broadest at that extremity which is nearest the vulva; but the womb, in a state of incomplete prolapsus, forms a tumour which is narrower below than above. With very few exceptions, the womb is likewise reducible, and the patient directly afterward feels great relief; whereas a polypus cannot be pushed back, and the attempt, instead of giving relief, only increases the patient's sufferings.

In a complete prolapsus, no doubt can ever prevail about the real nature of the case, for whatever uncertainty the feel of the parts may create, none can ever remain when the swelling is distinctly visible.

Although Mauriceau, Saviard, and Monro have recorded instances of prolapsus uteri in maidens, such cases are exceedingly rare. The disease is hardly ever met with, except in women who have had children, and generally in those who have borne a great many. This particularity is ascribed by writers to the elongation of the ligaments of the uterus in women, in whom this organ has been repeatedly gravid. The same consideration may also account for the frequency of prolapsus uteri during the first months subsequent to parturition, especially as the womb remains for some time after labour more enlarged and heavy than natural. The disease is more common in thin than fat women, and is said often to take place in females when they suddenly change from a fat to a very emaciated state. The displacement is facilitated by a capacious vagina, by a great width of the lesser cavity of the pelvis, and the effects of tedious and profuse attacks of fluor albus. Prolapsus uteri has also been brought on by violent concussions of the body; the protracted efforts of vomiting, coughing, or crying, hard labour, and lifting or carrying heavy burdens. In what has been stated, one may discern the reason, why the affliction is so frequent among the lower classes of society, and why women, for a certain time after parturition, should avoid an erect posture, and every kind of exertion. In the treatment of prolapsus uteri, there are two indications: the first is to reduce the part; and the second is to keep it from falling down again.

In the incomplete prolapsus, the first indication is very easy of accomplishment; and, indeed, when the patient is placed on her back with her pelvis raised somewhat higher than her chest, the uterus often returns of itself into its natural situation again. At all events, the reduction may be immediately effected by pushing the uterus up into the pelvis with the fingers.

More difficulty generally attends the reduction of a complete prolapsus. Here the same posture is to be chosen as in the former case; but the legs and thighs should be bent. The rectum should also be first emptied with clysters. Sometimes, indeed, every attempt at reduction fails, notwithstanding the adoption of the most vigorous measures, the use of the warm bath, purgatives, venesection, low diet, fomentations, &c. Occasionally, the part is returned after a great deal of trouble; but owing to the long-altered state of parts, the reduction brings on worse symptoms than resulted from the continuance of the prolapsus. Such a case is recorded by Richter.—(*Bibl. der Chir. b.* 3, *p.* 141.) The patient's sufferings were so much increased by the reduction, and so obstinate a constipation came on, that it became absolutely necessary to let the uterus descend again. In any irreducible case, all that can be done is to support the swelling and prevent its increase with a suspensory bandage, and draw off the urine with a catheter whenever requisite. In these cases, the altered course of the meatus urinarius is to be remembered, and the catheter directed horizontally towards the rectum

When the displaced uterus is inflamed and considerably swelled, the attempt at reduction should be preceded by antiphlogistic remedies, the patient should be kept in bed, be put on a low regimen, be bled, take purgative medicines, use the warm bath, and drink diluent beverages, while emollient applications are made to the part itself. This plan of treatment has often been attended with complete success in cases of prolapsus uteri of long standing and considerable size. Ruysch disapproved of making any attempt to reduce the uterus while it was inflamed and swelled. He also thought that the operation should be postponed when the uterus was in an ulcerated state. However, Sabatier rightly observes, that as this complication is only accidental, and merely arises from the friction to which the tumour is exposed, and the irritation of the urine, the plan of immediately replacing the part cannot be attended with any danger. On the contrary, since the cause which produces and keeps up the ulceration will cease as soon as the reduction is accomplished, the sores will heal after the uterus is put into its natural situation again.

When a prolapsus uteri occurs in the early stage of pregnancy, this state should not let the practitioner neglect to reduce the part. Several instances are recorded, in which the reduction was successfully accomplished in pregnant women; and one case of this kind is reported by Giraud.—(*Journ. de Médecine, t.* 45.) When pregnancy is far advanced, or the disease is of long standing, the reduction is difficult. Perhaps, says Sabatier, it may be more prudent, in these circumstances, to let the uterus continue protruded than to disturb the mother and fœtus with reiterated attempts to reduce the part. The uterus, however, should not be left to itself; but be well supported with a suitable bandage, and the patient kept in bed. When the prolapsus uteri occurs at the period of delivery, every attempt at reduction is both useless and dangerous. In this case, the delivery of the fœtus should be expedited by gradually dilating the os tincæ, which, at the same time, should be carefully supported. The extraction of the placenta also requires a great deal of caution, and it should be accomplished by introducing one hand into the uterus, with the palm turned away from the cavity of this viscus towards the outside of the placenta, which is to be gradually separated from its edges towards its centre.

In cases of complete prolapsus uteri, Ruysch was an advocate for leaving the expulsion of the fœtus, if alive, to be effected by nature; and the same writer advises us to be content with supporting the os tincæ. But when the child is dead, he recommends extracting it with one hand, while the uterus is supported with the other. Sabatier, however, entertains different sentiments. The expulsion of the child, he says, is not less the effect of the contraction of the diaphragm and abdominal muscles, than of the womb itself. Hence, when either of these agents fails to co-operate, the delivery becomes either very difficult or impossible. This is exactly what happens in the present case; for the uterus having fallen down, cannot be compressed by the diaphragm and abdominal muscles. Nor can Sabatier discern the reason why Ruysch should recommend the line of conduct to differ, according to the different state of the child. This is quite passive in parturition, and contributes not in the least to its own expulsion.

The second indication, or that of keeping the uterus reduced, demands the employment of astringent injections and pessaries.

The uterus in a state of prolapsus, is sometimes also affected with scirrhus and cancer. A case of this description was met with by Ruysch; and, very recently, a woman whose uterus was cancerous, and in a state of complete prolapsus, without any inversion, was attended by Langenbeck, who succeeded in removing the diseased organ with a knife, and the patient recovered. According to this author's description, after the vagina had been separated from the uterus, the latter organ was detached from the peritoneum without the latter membrane being opened, a small portion of the fundus uteri being left, however, as it appeared quite sound. The bleeding was very profuse, and required the use of the needle and ligatures. The ovaries and divided ligamenta rotunda, were found connected with the removed portion of the uterus.—(*Bibl. für die Chir. b.* 1, *p.* 551, 12*mo. Hanover*, 1818. *Sa-*

Hysteroptose.*)

UTERUS, RETROVERSION OF, is said to happen when its fundus falls downwards and backwards, between the rectum and the posterior part of the vagina, while its cervix inclines upwards towards the symphysis pubis. The ancients are thought to have had some imperfect notions of this case, and in proof of this opinion, certain passages are referred to in Œtius (*Tetrab.* 4, *Serm.* 4, *c.* 77), Mercurialis, Mercatus, and others.—(See *Dict. des Sciences Méd. t.* 23, *p.* 273.) Be this as it may, it is generally confessed, that the subject had fallen into oblivion when Dr. Wm. Hunter called the attention of his pupils to the subject in 1754, and afterward drew up an interesting paper concerning it.—(*Med. Obs. and Inquiries, vol.* 4, 8*vo. Lond.* 1771.) Subsequently the knowledge of the subject has been extended by the observations of Wizezeck (*De Utero retroflexo, Prag.* 1777), the remarks of Richter (*Chir. Bibl. b.* 5, *p.* 521, *and b.* 9, *p.* 182), and those of Wall (*Diss. de Uteri Retroversione, Hal.* 1782), and by the memoir of Desgranges, to which the prize of the Royal Academy of Surgery at Paris was adjudged, in the year 1785. According to Sabatier, retroversion of the womb was a case mentioned by Gregoire in his private lectures on midwifery at Paris.

Walter Wall, an English surgeon, who had attended Gregoire, suspected that he had met with a retroversio uteri in a woman, some months advanced in pregnancy, and he called in Dr. Hunter, in order that he might have the benefit of his advice. However, she was attacked with an obstinate constipation, and retention of urine, and died in about a week. A large tumour was found occupying the whole of the pelvis, and pushing the vagina against the os pubis. It had been found impracticable to push the swelling back into the abdomen, although the patient had been put on her knees and elbows, while one hand had been introduced into the vagina, and two fingers of the other hand into the rectum. Great curiosity existed about what information would be afforded by dissection. On opening the body, the bladder, which was exceedingly full of urine, filled almost the whole anterior part of the abdomen, in the same manner as the uterus does in the last month of pregnancy. When it had been emptied, that part of it in which the ureters terminate, and which is connected with the vagina and cervix uteri, was found raised up as high as the upper aperture of the pelvis, by a large tumour, which filled the whole cavity of the pelvis, and was found to be the uterus. A catheter, when passed into the vagina, could be made to lift up the latter viscus and the upper part of the tumour. This portion of the swelling on which the bladder lay, consisted of the cervix uteri, while the fundus of this organ was situated downwards towards the os coccygis and anus. The uterus was so large that it could not be taken out of the pelvis before the symphysis pubis was divided, and the two ossa innominata were pulled asunder. It was found impossible to assign any cause for the displacement of the uterus, as the patient had been making no exertion, and had met with no fall, though she is said to have been frightened at something just before the complaint commenced.

Dr. Hunter, struck with the singular nature of the case, thought it deserving of the attention of medical men, and he made it the subject of a lecture, which he delivered in 1754. He was afterward consulted by several persons who were afflicted with retroversio uteri; but not in so acute a way as in the above instance. All the patients were in the third month of pregnancy, and first suffered a difficulty of making water, succeeded by retention of urine, and afterward by tenesmus and constipation. Dr. Hunter always emptied the bladder and rectum by means of a catheter and clysters, which measures sometimes effected a cure the uterus spontaneously resuming its natural position. In every instance the accident disappeared when pregnancy was more advanced, and the uterus had acquired larger dimensions. In some cases, in which Dr. Hunter was consulted too late, the trials to empty the bladder and replace the uterus proved fruitless, and the women died. Dr. Hunter was so firmly convinced of the impossibility of saving patients circumstanced in the above manner, unless extraordinary means were resorted to, that he thought that an endeavour should be made to diminish the size of the uterus, by introducing a trocar into the body of this viscus through the posterior parietes of the vagina, so as to let out the water of the amnios, the relative quantity of which is known to be greater in the early than in the advanced stage of pregnancy.—(See *Journ. de la Faculté de Méd. p.* 173, *an* 1812.)

Such a puncture might certainly be the means of bringing the uterus back into its natural position; but not without considerable danger of abortion being produced. No risk of this kind would be encountered by puncturing the bladder above the pubes. In this manner, a free passage would be afforded for the escape of the urine, and the reduction of the uterus might then be effected. The suggestion of puncturing the uterus, I believe, has never been put in practice, and my opinion coincides with that of Mr. Weir, who thinks that it never will. A more justifiable mode of discharging the fluid would be by opening the membranes through the os tincæ, if such evacuation were deemed prudent.—(*Glasgow Med. Journ. vol.* 1, *p.* 268.)

Mr. Lynn, a surgeon in Suffolk, knew an instance of the bladder bursting, and the urine becoming fatally extravasated in the abdomen, in a case of retroversion of the uterus, in consequence of the patient's refusal to submit to paracentesis of the bladder.

Retroversio uteri does not often happen, except in the third or fourth month of pregnancy, and in women whose pelvis is very wide while the brim is much contracted. If the uterus, in a pelvis of this conformation, be pushed back by a distended bladder and pressed against the sacrum, while the soft parts yield, it becomes, as it were, wedged, and is incapable of changing its position. in this immoveable state it presses upon the surrounding parts, and these upon it, so that a very serious train of bad symptoms is the consequence.

It must not be supposed, however, that retroversion of the womb occurs only in pregnant women. Sweighauser and Schmidt had even seen it more frequently in unimpregnated females.—(See *Richter's Chir. Bibl. b.* 5, *p.* 132; *b.* 9, *p.* 310.) As Mr. Weir has remarked, pregnancy is not always necessary for the production of this affection, although he conceives that the womb must be in a certain degree enlarged, either by pregnancy or disease, before it can become retroverted. "Desault," he observes, "relates an instance produced by a polypus, and I have seen a case, where there was chronic enlargement of the uterus, but no impregnation. Mr. C. Bell mentions a fatal case of obstruction of urine, as having occurred in the practice of Mr. Cheyne, where, on examination of the body after death, the womb was found enlarged by disease, which had produced the same effect as if enlarged from pregnancy; for its fundus had fallen into the hollow of the sacrum, and had formed adhesions to the rectum, while the os uteri, pressing upon the urethra, caused the obstruction. Mr. Pearson (*Obs. on Cancerous Complaints, p.* 113) mentions a case of retroversion where the womb was enlarged from cancer. The patient, with a view of curing the cancerous affection, adhered most rigidly to a diet composed of liquids only, and, in the course of four weeks, the severe pains were completely removed, the uterus reduced in size, and restored to its natural position. Dr. Burns mentions that retroversion may take place "whenever the womb is enlarged to a certain degree by disease."

"Retroversion may also occur a short time after delivery, when the uterus is of that size which predisposes it for being thrown out of its true situation." Mr. Weir also adverts to a case, reported to him, in which a retroversion happened two days after delivery. The same occurrence is noticed by Callisen, and most of the cases recorded by Dr. Merriman are of this description.—(See *Glasgow Med. Journ. vol.* 1, *p.* 262.) It is questionable whether the uterus in a perfectly

healthy state can ever become retroverted. Dr. Denman was of opinion, that the case is possible; but this is contrary to what is usually believed, and requires the confirmation of facts. One of Mr. Weir's cases happened in a female 48 years of age, just after the catamenia had permanently ceased; and Dr. Merriman has known of similar examples. At this crisis, the circumstance of the uterus being apt to enlarge and grow heavy, may explain the reason of its displacement.—(See *Glasgow Med. Journ. vol.* 1, *p.* 265.)

The first care of a practitioner, consulted in a case of retroversio uteri, should be to empty the bladder and large intestines, and to relax the parts by every possible means. Then he should immediately proceed to reduce the uterus by placing the patient in a suitable posture, and making methodical pressure in the rectum and vagina. Should he be so fortunate as to succeed, the patient is to be confined in bed, her bowels are to be kept open, and she is to be advised always to obey the calls of nature the first moment she is conscious of them.

She is also to be enjoined to avoid all kinds of exertion, and wait till the gradual enlargement of the uterus removes the possibility of its descending into the pelvis.—(*Sabatier, Médecine Opératoire, t.* 2.)

Some practitioners, of considerable eminence, rather discourage the manual interference to reduce the uterus, believing that drawing off the urine will generally render such interference unnecessary.—(*Croft, in Lond. Med. Journ. vol.* 9, *p.* 53. *Denman's Midwifery*, 4*to. Lond.* 1801. *Burns's Midwifery. S. Merriman on Retroversion of the Womb*, 8*vo. Lond.* 1810.)

This difference of practice arose from the different views taken of the cause of the displacement of the womb. Dr. Hunter believed, that the retroversion was the cause of the retention of urine, and of all the other symptoms. On the contrary, Dr. Denman argued, that the retention of urine was the first symptom, and that the consequent enlargement of the bladder raised the neck and mouth of the womb, and caused the fundus to fall backwards; in which position its pressure on the urethra and rectum kept up the retention of urine, tenesmus, difficulty of emptying the bowels, &c.

In one case, under Mr. Weir, although the urine was repeatedly drawn off by means of a catheter, with some difficulty, the uterus could not be reduced until an assistant pushed its fundus upwards, with his hand passed into the rectum; while Mr. Weir himself cautiously drew down the mouth of the womb. Abortion followed; but the patient recovered.

I have adverted to the case where Dr. Hunter could not succeed in the reduction; and where, after death, the uterus was so fixed in the hollow of the sacrum, that it could not be replaced until the symphysis of the pubes had been divided. But, as Mr. Weir remarks, the reduction may in general be easily accomplished when attempted early; and although it has been asserted, that forcible attempts will be very apt to produce abortion, or even worse consequences, he is not aware of any case on record, where bad effects were fairly attributable to the manual efforts. Abortion has, no doubt, occurred; but this, he argues, was the consequence of the disease, or deemed absolutely necessary to effect the reduction. He admits that violent and unnecessary attempts are not justifiable; but he contends that if the retroversion be complete, and dangerous symptoms be present, the uterus must be replaced at every risk. Our efforts, he thinks, should be in proportion to the difficulty to be overcome. He is aware, that cases have occurred in which the uterus could not be moved. Besides the case quoted above from Dr. Hunter, where the fundus of the womb could not be got out of the sacrum even in the dead subject, until the symphysis of the pubes had been divided, he states, that the same thing happened in a patient who had been under Dr. Perfect (*Perfect's Cases in Midwifery, vol.* 1, *p.* 394); and in a singular case, related by Mr. White, of Paisley (*Med. Communications, vol.* 20), many attempts to replace the womb were made in vain. Here, however, the uterus was enlarged from disease as well as one of the ovaries. The patient recovered after much danger, and the bursting of an abscess of the ovary into the rectum. "The advocates for non-interference have asserted (says Mr. Weir), that the catheter can, in general, be easily introduced; and that the distention of the bladder, which is the *cause* of the retroversion, being thus removed, all chance of danger is obviated; and one author mentions, that no case will ever occur where the urine cannot be drawn off. Now, the cases already referred to clearly show, that, in general, there will be more or less difficulty in introducing the catheter; and there are some on record, where it was found impossible. In Dr. Cheston's (*Med. Commun. vol.* 2, *p.* 96), Mr. Lynn's (*Med. Obs. and Inq. vol.* 4), Dr. Squire's (*Med. Review*, 1801), M. Baudelocque's (*L'Art des Accouchemens, sect.* 253), Doeverius's Case (*Merriman on Retroversion, p.* 12), Mr. Combe's (*Med. Comment. vol* 5), and Dr. Perfect's (*Cases, vol.* 1, *p.* 394), the urine could not be drawn off. In the first, the bladder was punctured above the pubes; and in four the bladder burst.

Mr. Weir, as I conceive, with great reason, doubts the correctness of the doctrine, that the distention of the bladder is the first cause of the retroversion. When this takes place, a full state of the bladder may certainly tend to increase it, and to prevent the reduction of the uterus. He considers Dr. Hunter's opinion as most correct; namely, that some degree of displacement first occurs, and that this brings on the retention. He adverts to cases in which the urine was regularly drawn off for several weeks, and the distention of the bladder removed, yet the uterus did not rise. In Dr Bell's case (*Med. Trans. vol.* 8), the urine was drawn off regularly; but the uterus continued retroverted, and was the remote cause of an inflammatory affection of the abdomen, which proved fatal. Sir A. Cooper has also referred to one of Dr. Marcet's patients, from whom the urine was discharged regularly; yet the consequence of allowing the womb to remain retroverted was the death of both mother and child. Another example is also cited (*New-York Med. Repository, vol.* 40), where the urine was never obstructed at all, and where the retroversion continued for some months till the woman died.—(See *Weir, in Glasgow Med. Journ. vol.* 1.)

[UTERUS, INVERSION, PROLAPSUS, AND RETROVERSION OF THE. These disorders, as well as rupture of the womb, which is not at all noticed, might have been treated of at length by our author, inasmuch as they exercise a vast influence on the female economy, and are the fruitful source of many serious affections; but they are, doubtless on account of their more close connexion with another department of the profession, dismissed in the manner we see in the text. The reader will find some most interesting observations on displacements of the womb, and on the sequela of those disorders, in the admirable work of Charles Mansfield Clark, entitled, "Observations on the Diseases of Females attended with Discharges," and also in the System of Midwifery and on Female Diseases, by the distinguished Professor Dewees, of Philadelphia. See also Ramsbottom's Midwifery, and the edition of Denman's Midwifery, with notes and emendations, by Professor Francis, of New-York, third edition, 1829. A valuable paper on rupture of the uterus, by Professor James, may be seen in the New-York Medical Repository, vol. 7, and a judicious essay on the same subject, by Dr. Church, in the American Medical Review, vol. 3. In this last paper Dr. Church satisfactorily shows, that too great discrepancy exists in the writings of the best writers on the pathological signs of this lamentable accident.—*Reese.*]

Journ. vol.* 1, *p.* 262, *&c. This last paper is full of practical information, and merits careful perusal.*

UVA URSI, which was first brought into notice by De Haen, was once considered a powerful remedy in calculus; but, though its virtue in lessening the irrita-

tion of the bladder is still acknowledged, its claim to utility on any other principle is quite rejected. Dr. Austin recommended it for lessening the irritability of the bladder, and diminishing the secretion of diseased mucus, which, he supposed, greatly contributed to the augmentation of the stone.

Mr. B. Bell also strongly recommended it in gonorrhœa, where the irritability of the bladder was excited in a high degree, and where the urine was loaded with viscid matter. In these cases, he directed a scruple or half a drachm of the powder three times a day.

Dr. Saunders used to order three drachms of uva ursi to be macerated in a pint of hot water, and two or three ounces of the strained liquor to be given three times a day.—(*Pharm. Chirurg.*)

UVULA, AMPUTATION OF. The uvula is subject to several kinds of enlargement, in which it becomes both longer and more bulky than natural, or is simply lengthened. In consequence of such changes, it becomes troublesome in deglutition and speaking, and causes a disagreeable tickling at the root of the tongue, frequent retchings, and an annoying cough.

When things have attained this state, medicines are often ineffectual, and the only plan of relief consists in amputating a portion of the uvula with a pair of scissors. I lately amputated a gentleman's uvula, on account of an obstinate and deep ulceration, extending nearly through its root and producing a lateral displacement of the part, attended with a considerable degree of irritation and annoyance.

V

VAGINA IMPERFORATE. Female infants are often born with different imperforations of the vagina. Sometimes this passage is not completely shut up, the usual evacuations happen in an uninterrupted manner, and it is a considerable time before the malformation is discovered. Some females are even stated to have become pregnant, notwithstanding such obstruction; and in these cases, the membrane, which shut up a part of the mouth of the vagina, was either torn by the effects of labour, or divided as much as was necessary for delivery.

Two membranes, one placed beyond the other, and obstructing the vagina, have also been found. That which is commonly met with, is only the hymen, thicker and stronger than natural. Ruysch describes the case of a woman, who had been in labour three days, and could not be delivered. The head presented itself, but was prevented from coming out by the hymen, which shut up the vagina, and was very tense. Ruysch made an incision into the membrane; but to no purpose, since there was another membrane of a thicker texture, situated more deeply in the passage. As soon as this second membrane had been divided, the child was expelled, and the case ended well.

When the vagina is completely imperforate, and the time of the menses commences, many complaints occur which afflict the patient with more severity, in proportion as the blood accumulates in the passage, and they may even lead to a fatal termination, when the cause is not understood or not detected till it is too late. These complaints are very similar to those of pregnancy; for instance, rumbling noises in the bowels, loss of appetite, nausea, vomiting, enlargement of the mammæ, spasms, convulsions, swelling of the abdomen, &c. Hence, girls in this situation, have often been supposed to be pregnant, although they were not in a state even to become so; and some young women have been known to die after dreadful sufferings.

When the malformation consists altogether in the orifice of the vagina being shut up by a membrane, the patient may be easily relieved by a crucial incision or a single cut, the edges of which are kept apart by a tent of suitable shape and size. Instances of the success of such an operation are to be found in numerous writers. Fabricius ab Aquapendente informs us that a female child was born with a membrane, which completely shut up the vagina. The girl experienced no inconvenience from it till she was about thirteen, when the period of her menses began. As the blood was retained, she became afflicted with severe pains in the loins, the lower part of the abdomen, and about the upper part of the thighs. She was supposed to be attacked with sciatica, and treated accordingly. Medicines were prescribed which did no good; and, at length, she became hectic, and reduced to a complete state of marasmus, in which she passed restless nights, lost her appetite, and was delirious. A painful, very elastic tumour afterward presented itself in that part of the abdomen, which corresponds to the uterus. The pains were aggravated every month, at the period when the patient ought to have menstruated. She was in a dying condition, when Fabricius ab Aquapendente was consulted, who, after ascertaining the real nature of the case, performed the requisite operation. A prodigious quantity of black putrid blood was discharged from the vagina; the bad symptoms gradually subsided, and the patient recovered.—(See also *J. C. Loder, Obs. Imperforationis Vaginæ, Icone illustrata, 4to. Jenæ*, 1800; *and numerous other cases on record.*)

When the malformation is produced by an extensive concretion of the sides of this passage to each other, the cure is sometimes difficult. The result of the operation is doubtful, because it is impossible to reach the confined menstrual fluid, without cutting through a considerable thickness of parts, in doing which there is some danger of wounding the rectum or bladder. A lady, twenty-four years of age, after having tried for eight years such remedies as seemed best calculated for exciting the menstrual discharge, became affected with a large hard swelling of the abdomen, and a kind of herpetic affection round the body near the navel. At length it was discovered, that the imperforation of the vagina was the sole cause of all the bad symptoms which the patient had long endured. An incision was made, which enabled the operator to introduce his finger into a large cavity, and which gave vent to a considerable quantity of blood. It was thought that an opening had been made into the vagina; but the patient having died three days afterward, it was seen that a mistake had been made, as the cavity in which the finger had been introduced was that of the bladder. The vagina was closed below by a substance, one inch in diameter, and half an inch thick. The upper part of this passage, the uterus, and the Fallopian tubes were exceedingly enlarged, and filled with a dark-brown sanious fluid. A similar fluid was found extravasated in the abdomen, through a rupture, which had taken place in the Fallopian tube. The ovaries were in the natural state. De Haen, who has related this case in the sixth part of his work, entitled *Ratio Medendi*, was of opinion, that in order to avoid opening the rectum or bladder, only one oblique cut should be made in the membrane which stops up the vagina, just as was advised by Méeckren.—(*Sabatier de la Médecine Opératoire, t.* 1.)

VAGINA, PROLAPSUS OR INVERSION OF. According to Sabatier and Levret, the lining of the vagina is alone displaced; but Richter, Chelius, and other writers describe the vagina as liable to two kinds of prolapsus: in one, all its tunics are included in the protrusion; in the other, only its relaxed lining. It is only in this last case, that the uterus may not be involved in the prolapsus.—(*Chelius, Handb. der Chir. b.* 1, *p.* 771.)

Occasionally, a prolapsus of a very limited portion of the vagina is observed. This case is generally the consequence of an uncommon sort of rupture, termed the *vaginal hernia* (see *Hernia*); but it should also be known that, in some cases of dropsy, a circumscribed protrusion of the vagina in the form of a cyst or pouch, filled with fluid, is sometimes noticed.

When the prolapsus vaginæ is recent, the part may be easily reduced and kept up with a pessary. The use of astringent lotions will then tend to prevent a relapse. But when the case has been of long standing, it is neither easy to effect the reduction nor to prevent a recurrence of the disorder. Softening, relaxing re-

medies, in this circumsta ce, are recommended, and the patient should, in particular, confine herself to her bed, and wear a T bandage, which should be made to press upon and support a piece of sponge in the orifice of the vagina.

It is reasonable to expect that, after a prolapsus vaginæ has continued a long while, the reduction must be difficult; because the vagina in this state becomes affected with swelling and induration. According to the reports of Hoin and Levret, a large protrusion of this kind, ten inches in length, was so diminished by keeping the patient invariably confined in bed upon her back, that in the course of a month, the rest of the tumour admitted of being reduced. Indeed, as Richter observes, there can be little doubt that the treatment which has been advised by some authors for the diminution of very old, enormous, omental ruptures, would here be equally applicable; viz. long confinement in bed upon the back, with the buttocks somewhat elevated; unremitting well-directed external pressure; a very low diet; and repeated mercurial purges.

During pregnancy, a prolapsus of the whole substance of the vagina may cause much embarrassment and even danger. In one case of this description, where the protrusion was five inches in length, it became necessary to turn the child, and the displaced vagina was lacerated. The woman, however, recovered.—(*Pietsch, Journal de Méd. t.* 34.) In another instance, where the prolapsus became, at each return of the labour-pains, as large as a man's head, the practitioner succeeded in holding the parts back, while delivery was effected with the aid of the forceps.—(See *Loder's Journ. b.* 1, *p.* 490.) When this is impracticable, it is necessary, according to Richter, to make an incision through both sides of the prolapsus; a measure, says he, to which the practitioner may the more readily make up his mind, inasmuch as the parts have, in some cases, been lacerated without any ill consequences.

A prolapsus of the inner membrane of the vagina while small and recent, might perhaps be removed by astringent applications. When, however, it is of long standing, indurated, and of large size, much expectation of success from this treatment cannot be entertained. Richter sees no reason why, in such a case, the superfluous relaxed part should not be cut away, especially if the disease be accompanied with ulceration and other serious complaints. As he observes, there can be no doubt that a prolapsus of the inner membrane of the vagina, when limited to one part of this canal, may always be safely extirpated, either with a knife or a ligature.—(*Anfangsgr. der Wundarzn. b.* 7, *chap.* 4; *J. C. Loder, Progr.* 1—3. *De Vaginæ Uteri Procidentia; Jen.* 1781. *M. J. Chelius, Handb. der Chir. b.* 1, *p.* 770, *Heidelb.* 1826.)

VARICOCE'LE. (From *varix*, a distended vein, and *κήλη*, a tumour.) Many writers mean by the term *varicocele*, a varicose enlargement of the spermatic veins, which latter affection I have, with Celsus and Pott, treated of under the name of *Cirsocele*.

Pott remarks, that the varicocele (which is an enlargement and distention of the blood-vessels of the scrotum) is very seldom an original disease, independent of any other, and when it is, that it is hardly an object of surgery. The original disease is what engages our attention, and not this simple effect of it.—(*Pott's Chirurgical Works, vol.* 2.)

VARICOSE VEINS. The term *varix* is applied by surgeons to the permanently dilated state of a vein, attended with an accumulation of dark-coloured blood, the circulation of which is materially retarded in the affected vessel. When veins are varicose, they are not only dilated, they are also evidently elongated; for, besides being irregular, and in several places studded with knots, they make a variety of windings, and, coiling themselves, form actual tumours.

Varices are most commonly observed in the lower extremities, reaching sometimes even as far up as the abdomen. They have, however, been noticed in the upper extremities, and it is probable that the whole venous system is susceptible of the affection. As a well informed writer observes, "the great venous trunk sometimes becomes varicose. When the disease is situated near the heart, it is attended with pulsation, which renders it liable to be mistaken for aneurism. Morgagni observed, that the jugular veins were occasionally very much dilated, and possessed a pulsation —(*Letter* 8, *art.* 9, 10, 11.) He also relates a case in which the vena azygos, for the length of a span, was so much dilated that it might be compared with the vena cava. The patient died suddenly in consequence of the rupture of this varix into the right side of the chest.—(*Letter* 26, *art.* 29.) A similar case is related by Portal, who also mentions an instance in which the right subclavian vein was excessively dilated and burst into the chest.—(*Cours d'Anatomie Medicale, tom.* 3, *p.* 354. 373.) Mr. Cline described in his lectures the case of a woman, who had a large pulsating tumour in her neck, which burst and proved fatal by hemorrhage. A sac proceeded from the internal jugular vein; the carotid artery was lodged in a groove at the posterior part of this sac. The veins of the upper extremity very rarely become varicose. Excepting cases of aneurismal varix, the only instance of this disease with which I am acquainted, is mentioned by Petit.—(*Traité des Maladies Chir. tom.* 2, *p.* 49.) In this case a varix was situated at the bend of the arm: the patient was so fat that no other vein could be found for the purpose of venesection, which operation Petit repeatedly performed by puncturing this varix. The superficial epigastric veins sometimes become varicose, but the most frequent seats of this disease are the venæ saphenæ, the spermatic and hemorrhoidal veins."—(See *Hodgson's Treatise on the Diseases of Arteries and Veins, p.* 538, 539.) The deep-seated veins of the extremities seldom become varicose. The disease rarely occurs before the adult period of life, and its progress is extremely slow. It is very frequently remarked in pregnant women, who have passed a certain age; but it is particularly unusual for it to happen in young women, even during a series of repeated pregnancies. Surgeons have not hitherto made out any very precise information respecting the kinds of constitution which promote the occurrence of a varicose enlargement of the veins. Nor has it been well proved that the disease often proceeds from swellings of the abdominal viscera, or any other species of tumour capable of mechanically obstructing the venous circulation. One or more veins of the same limb are at first most commonly affected with a slight degree of dilation, without pain or any sensation of uneasiness. This beginning change ordinarily advances with great slowness, except in cases where it accompanies pregnancy, in which circumstance one or both the lower extremities, as early as the first months, are frequently seen covered with largely dilated veins, or even with tumours formed by an assemblage of varices. The veins gradually become more and more distended, lengthened, coiled up, and tortuous. The patient then begins to complain of a sense of heaviness, numbness, and sometimes of very acute wandering pain through the whole of the affected limb. In a more advanced age, in proportion as the varices increase, and especially when the dilated veins actually form tumours, the limb swells and becomes more or less œdematous, according to the extent of the disease, and the time which it has existed. Delpech thinks, however, that the œdema in this case is not such as to justify the conclusion, that the increased size of the veins, and the way in which they distend the integuments, produce a mechanical interruption of the function of the absorbent system. For, says he, enormous varices are sometimes, though not often, met with, which are not attended with any swelling of the cellular substance; and cases are still more frequently seen in which there is a considerable degree of œdema, while the varices are scarcely remarkable. When the latter have prevailed a long while, and made much progress, the coats of the affected veins are not unfrequently thickened, swelled, and indurated, forming a sort of half-canal or solid tube. As Mr. Hodgson remarks, "the blood occasionally deposites strings of coagulum in varicose veins; when this is the case, the vessel is incapable of being emptied by pressure, and is firm to the touch. The deposition does not in general fill the vessel, but by diminishing its caliber, it retards the flow of blood, and causes the dilatation to increase in the inferior portion of the vein, and in the branches which open into it."—(*On the Diseases of Arteries and Veins, p.* 541.) This gentleman has seen four cases, in which the coagulum accumulated to such an extent, that the canals of the dilated vessels were obliterated, and a spontaneous cure was the consequence

The excessive distention of the coats of a superficial vein produces an inflammatory irritation, at first in the adjoining cellular membrane, and afterward in the integuments. These textures become at first connected together by the adhesive inflammation; and if the distention continue to operate, they may at length ulcerate and burst, and hemorrhage be the consequence. In such cases, the effusion of blood is sometimes considerable; but, says Delpech, we have no example of its having proved dangerous. The syncope following it, or a moderate compression, suffices for its stoppage. A more common occurrence than bleeding is the coagulation of the blood in the cavity of a varicose vein. The vessel then becomes hard and incompressible, and it loses that elastic yielding softness which renders it capable of being diminished by gentle pressure. If the parts be already inflamed, Delpech conceives that the clot in the diseased vein may act as an extraneous body, and bring on ulceration by the effects of which it is at last brought into view. In this sort of case, it is extremely uncommon for hemorrhage to occur; for, in general, the vessel is already obliterated by the preceding inflammation. But the ulcer itself is very difficult to heal, and may be kept up a long while by the œdematous swelling of the limb. Varices, or rather the œdema, which is the consequence of them, have the same effect upon every other species of ulcer, and even upon the most simple solution of continuity. While the swelling of the limb cannot be dispersed; while the edges of a solution of continuity are kept asunder by the tense state of the skin; and while the divided parts are irritated by this painful tension; every thing is unfavourable to cicatrization. Thus we see the most simple wounds, which have been allowed to suppurate, and ulcers, which should have healed rapidly, continue uncured a great many years, merely because the limbs on which they are situated are affected with an œdematous swelling, the consequence of varices. Such is the condition of things in the case which has been improperly named the *varicose ulcer*.—(*Delpech, Precis des Maladies Chir. t.* 3, *sect.* 8, *art.* 3.)

In the investigation of the causes of varices, it is usual to dwell very much upon the mechanical obstructions which may affect the circulation of the blood in the veins. Surgeons have thought themselves justified in regarding this as the only cause, because a circular moderate compression incontestably retards the course of the blood in these vessels, and produces a temporary dilatation of them. The opinion seems also to derive confirmation from the knotty appearance of varicose veins; a circumstance which has been accounted for by supposing that the distention is greatest in the situation of the valves. Lastly, the idea is farther supported by the well-known fact of the frequent occurrence of varices during the state of pregnancy. But it has not been remembered that the use of garters, for example, is extremely common, yet varices of the legs are infinitely less frequent; that very large varices are met with in persons who have never employed any kinds of ligatures, to which the origin of the complaint can be imputed; that when the dilatation of the veins extends to the thighs and parietes of the abdomen, no causes of this description even admit of suspicion; that varicose veins are observable round several kinds of tumours, especially scirrhi, when there is no possibility of pointing out any mechanical obstruction to the circulation of the blood; that varices sometimes make their appearance at the commencement of pregnancy, and long before the enlargement of the womb can impede the free return of the blood through the veins in the pelvis; that nothing is more unusual than a varicose dilatation of the veins of the lower extremities in consequence of swellings of the abdominal viscera; and, lastly, it has been forgotten, that the knots of the dilated veins are far too numerous to admit of being ascribed to the resistance of the valves. It cannot be denied, that pressure applied in the track of the vessels tends to promote their dilatation; but it can neither be considered as the only cause, nor as the principal one. The foregoing observations, made by Delpech, render it probable, that some unknown general cause is concerned in producing varices, the formation of which may also be facilitated by the impediments to the free return of the blood occasioned by certain attitudes and particular articles of clothing.

Mr. Hodgson conceives it probable, that, in some instances, the valves are ruptured in consequence of muscular exertions or external violence, in which cases the pressure of the column of blood is the first cause of the dilatation of the veins. Sometimes also the disease appears to arise from preternatural weakness in the coats of the veins, as in those instances in which, without any evident cause, it exists in various parts of the same person.—(*Treatise on the Diseases of Arteries and Veins*, *p.* 537.)

Experience proves, says Delpech, that there is no certain mode of curing *varices*, strictly so called, which he thinks cannot be wondered at, since the nature and causes of the disease are completely unknown. The same source of knowledge, however, also proves that the increase in the dilatation of varicose veins may be retarded, and that the œdematous swelling attendant on the complaint may be beneficially opposed by methodical and permanent compression. When the whole of a limb affected with varices is subjected to this last mode of treatment, the dilated veins subside, the circulation is more regularly performed, and the œdema and pain cease. There is not (says Delpech) any better method of healing the solutions of continuity in the soft parts, produced or kept up by the varicose state of the limb and its consequences. But sometimes, as soon as the compression is discontinued, the varices make their appearance again, the pain recurs, the œdema returns, and the ulcers which were healed break out afresh.

Inflammation of the integuments covering a varix or varicose tumour cannot invariably be prevented by compression, nor will this treatment always succeed even in removing the intolerable pain which sometimes attends numerous clusters of varicose veins. In the first case, rest and relaxing applications will often succeed; and in the second, the topical use of sedatives frequently gives relief. It has been proposed to puncture and empty varicose veins; but if a temporary emptiness and relaxation of these vessels were to remove the pain for a time, things would fall into the old state again in the course of a few days. If the plan were adopted, it would be necessary to make a very free opening in the dilated vein, and extract the coagulum. The vessel would then need no ligature above and below the opening, for the slightest compression would afterward stop the bleeding, and the vessel be obliterated by the subsequent inflammation. Graefe's plan, indeed, consists in making an incision two inches long through the integuments and coats of the largest knotty part of the vein, stopping the bleeding by pressure with the finger, filling the exposed cavity of the vein with lint, and then applying a compress and roller. When the varices are confined to the leg, one incision of this kind is set down by Graefe as sufficient; when they reach to the middle of the thigh, he practises one incision above the ankle, and a second a little above the knee; and, if the whole of the thigh be affected, he makes a third incision in the upper part of the limb. A bandage and cold lotions are to be applied for a few days. The result is, that an inflammation follows, which spreads from the large varicose veins to the surrounding ones in a sufficient degree to bring about their subsidence.—(See *Graefe's Preface to the German Transl. of C. Bell's Surgery.*) Chelius deems this plan of treatment preferable to that of exposing the venous trunk and injuring its coats.—(*Handb. der Chirurgie*, *b.* 1, *p.* 888.)

We learn from Celsus that the ancients were accustomed to remove varices by excision, or destroy them with the cautery.—(*De Re Medica*, *lib.* 7, *cap.* 3.) When the vein was much convoluted, extirpation with the knife was preferred; but, in other cases, the dilated vessel was exposed by an incision, and then cauterized. Petit, Boyer, and many British surgeons have also sometimes cut out clusters of varicose veins.

Delpech remarks, that the extirpation of tumours composed of numerous varices has been practised, either for the purpose of removing the pain in the situation of the disease, or other inconveniences. This operation has been successfully performed; but it appears not to have constantly had the effect of preventing the formation of new varices, and it has sometimes proved tedious, difficult, and severely painful in its execution. In fact, an erroneous judgment must necessarily be formed of the extent of these swellings, when they are judged of only from the appearance which they

present under the skin. Varices are not always confined to the superficial veins, and, when they extend deeply, the operation must be ineffectual. The opinion of Delpech is, that it should never be undertaken, unless the disease be accompanied with perilous symptoms, or the patient nearly deprived of the use of his limb.

It has been thought, that one of the established principles in the treatment of aneurisms might be advantageously extended to the cure of varicose veins. By tying the principal venous trunk above the point to which the varicose affection reaches, it is said, that the course of the blood in the morbid vessels may be totally stopped, the column of this fluid made to coagulate, and the consequent obliteration of the vessels themselves accomplished.

The practice of tying veins for the cure of varices appears to have been employed in the days of Paré and Dionis (*Cours d'Operations de Chirurgie, p.* 610), who accurately describe the operation of tying and dividing the vein between the two ligatures. Sir Everard Home has related many cases of varicose veins in the leg, some of them accompanied with tedious ulcers, which, after the vena saphena major had been tied as it passes over the inside of the knee, were readily healed, and the dilatation of the veins of the leg relieved.

This practice has sometimes answered, but it has also had its failures.

Among other evils, an inflammation of the tied vein has been observed extending very far in the vessel, and succeeded by great constitutional disorder, symptoms very analogous to those of typhus fever and death. Sir A. Cooper in his lectures strongly deprecates it; he says that he has seen it twice prove fatal in the borough hospitals, and refers to at least a dozen other examples which had a similar end. In some of these cases, previously to their termination, abscesses form in the direction of the vessel either below or above the ligature; in others, such collections of matter are not observed.—(See *Travers on Wounds and Ligatures of Veins. Surgical Essays, part* 1, *p.* 216, *and Oldknow in Edinb. Med. and Surg. Journ. vol.* 5; *R. Carmichael, in Trans. of the King's and Queen's College of Physicians, vol.* 2, *p.* 345, *&c.*) Indeed, the dangers arising from an inflammation of the internal coat of the veins are now generally acknowledged, and every endeavour should be made to avoid them. A case which happened in Guy's Hospital in 1816 fully proves them; the femoral vein happened to be pricked in an operation for aneurism, and a ligature was applied round the aperture. Inflammation of its internal coat took place, extending up into the vena cava, and the patient is supposed to have died of the indisposition resulting from it.—(See *Travers's Surgical Essays, part* 1, *p.* 222.) The opinion of Mr. Arnott on this point will be noticed in the ensuing article, *Veins*.

Hence arises one of the most weighty objections to the practice of tying the trunks of varicose veins, with the view of curing their morbid dilatation, and its effects upon the limb.

As Mr. Brodie observes, it seems to be now established by the experience of modern surgeons, that a mechanical injury inflicted on the trunk of one of the larger veins is liable to be followed by inflammation of its internal membrane, and a fever of a very serious nature; and the occasional occurrence of these symptoms after the ligature, or even the simple division of the vena saphena, has made surgeons less confident than formerly of the propriety of attempting such operations for the relief of a varicose state of that vessel in the leg. Certain reflections, however, induced Mr. Brodie to think that the same ill effects would not follow a similar operation performed on the branches themselves. "Where the whole of the veins of the leg are in a state of morbid dilatation, and the distress produced by the disease is not referred to any particular part, there seem to be no reasonable expectations of benefit except from the uniform pressure of a well applied bandage. But, not unfrequently, we find an ulcer which is irritable and difficult to heal on account of its connexion with some varicose vessels; or, without being accompanied by an ulcer, there is a varix in one part of the leg, painful, and perhaps liable to bleed, while the veins in other parts are nearly in a natural state, or, at any rate, are not the source of particular uneasiness. In some of these cases, I formerly applied the caustic potash, so as to make a slough of the skin and veins beneath it; but I found the relief which the patient experienced from the cure of the varix, to afford but an inadequate compensation for the pain to which he was subjected by the use of the caustic, and the inconvenience arising from the tedious healing of the ulcer, which remained after the separation of the slough.

In other cases, I made an incision with a scalpel through the varix and skin over it. This destroyed the varix as completely as it was destroyed by the caustic, and I found it to be preferable to the use of the caustic, as the operation occasioned less pain, and as, in consequence of there being no loss of substance, the wound was cicatrized in a much shorter space of time. I employed the operation, such as I have described it, with advantage in several instances; but some months ago I made an improvement in the method of performing it, by which it is much simplified; rendered less formidable not only in appearance, but also in reality; and followed by an equally certain, but more speedy cure.

It is evident (says Mr. Brodie) that the extensive division of the skin over a varix can be attended with no advantage. On the contrary, there must be a disadvantage in it, as a certain time will necessarily be required for the cicatrization of the external wound. The improvement to which I allude consists in this: the varicose vessels are completely divided, while the skin over them is preserved entire, with the exception of a moderate puncture which is necessary for the introduction of the instrument with which the incision of the veins is effected. Thus the wound of the internal parts is placed under the most favourable circumstances for being healed, and the patient avoids the more tedious process, which is necessary for the cicatrization of a wound in the skin above.

For this operation I have generally employed a narrow, sharp-pointed bistoury, slightly curved, with its cutting edge on the convex side. Having ascertained the precise situation of the vein, or cluster of veins, from which the distress of the patient appears principally to arise, I introduce the point of the bistoury through the skin on one side of the varix, and pass it on between the skin and the vein with one of the flat surfaces turned forwards and the other backwards, until it reaches the opposite side. I then turn the cutting edge of the bistoury backwards, and, in withdrawing the instrument, the division of the varix is effected. The patient experiences pain, which is occasionally severe, but subsides in the course of a short time. There is always hemorrhage, which would be often profuse, if neglected, but which is readily stopped by a moderate pressure made by means of a compress and bandage carefully applied."

Mr. Brodie particularly enjoins the necessity of keeping the patient quietly in bed for four or five days after the operation, and removing the bandage and first dressings with the utmost care and gentleness. He also cautions surgeons not to make the incision more deep than absolutely necessary. Inflammation of the coats of the veins has not occurred in any of the cases in which Mr. Brodie has adopted this method of treatment. This gentleman wishes it to be understood, however, that he does not recommend the practice indiscriminately, but with a due attention to the circumstances of each individual case. "The cases for which it is fitted are not those in which the veins of the leg generally are varicose, or in which the patient has little or no inconvenience from the complaint; but those in which there is considerable pain referred to a particular varix, or in which hemorrhage is liable to take place from the giving way of the dilated vessels, or in which they occasion an irritable and obstinate varicose ulcer."—(See *Med. Chir. Trans. vol.* 7, *p.* 195, *et seq.*)

On the subject of cutting through veins affected with varix, it is proper to observe, that even this plan has been known to bring on severe and fatal symptoms. Cases confirming this fact are recorded in a valuable modern work, which should be in the hands of every practical surgeon.—(See *Hodgson's Treatise on the Diseases of Arteries and Veins, p.* 555, *et seq.*) It is but justice to state, however, that in these examples Mr. Brodie's manner of doing the operation was not adopted. On the contrary, his method, as far as I have

yet heard, receives very general approbation. Some cases and observations highly in favour of it are detailed by Mr. Carmichael.—(See *Trans. of the King's and Queen's College of Physicians, vol.* 2, *p.* 369, *&c.*)

Cases of spontaneous varix in the veins of the arm are rarely observed. When these vessels become varicose, it is almost always in consequence of a communication being formed, in the operation of venesection, between the brachial artery and one of the veins at the bend of the arm. The superficial veins in this situation then become more or less dilated by the impulse of the stream of arterial blood which is thrown into them. There is, however, a good deal of difference between these accidental varices actually induced by a mechanical cause, and those which originate spontaneously, or from causes not very clearly understood. The former never acquire the size which the latter often attain; they never exceed a certain magnitude, whether pressure be employed or not; they never form tumours composed of an assemblage of varicose veins; they are never filled with tough coagula of blood; their coats are never thickened, nor constitute the solid half obliterated canal remarked in the other species of varices; the skin which covers them is not disposed to inflame and ulcerate; they are not subject to occasional hemorrhage; and the limb is not affected with any œdematous swelling.—(*Delpech, Traité des Maladies Chir. t.* 3, *p.* 261.) These circumstances render it evident that here all surgical interference would be unnecessary.

See *Aneurism*, where the aneurismal varix is described; *Cirsocele*, where the varix of the spermatic cord is treated of; *Hemorrhoids*, where the diseased and enlarged veins of the rectum are considered; *Varicocele*, where those of the scrotum are noticed.

VARIX. (From *varius*, unequal.) The term *varices* is applied to a kind of knotty, unequal, dark-coloured swelling, arising from a morbid dilatation of veins.—(See *Varicose Veins.*)

VEINS, DISEASES OF. To the observations and references made in the preceding article (*Varicose Veins*), I here annex a few remarks on the principal diseases of the venous system, in order to render what has been already stated in other parts of the work more complete.

It is observed by Mr. Hodgson, that "the veins are liable to all those morbid changes which are common to soft parts in general; but the membranous lining of these vessels is peculiarly susceptible of inflammation. When a vein is wounded, the inflammation, which is the effect of the injury, sometimes extends along the lining of the vessel into the principal venous trunks, and in some instances even to the membrane which lines the cavities of the heart.—(See *Bleeding.*) This inflammation sometimes produces an effusion of coagulating lymph, by which the opposite sides of the vein are united, so as to obliterate the tube; in this manner, a great extent of the vessel is occasionally converted into a solid cord. In some instances, the secretion of pus into the cavity of the vessel is the consequence of inflammation of the membranous lining of a vein. Under these circumstances, the matter is either mixed with the circulating blood, or, the inflammation having produced adhesion of the sides of the vessel at certain intervals, boundaries are formed to the collection of pus, which in this manner form a chain of abscesses in the course of the vessel.

When the inflammation of veins is not very extensive, its symptoms are the same as those of local inflammation in general; but when the inflammation extends into the principal venous trunks, and pus is secreted into the vessel, it is accompanied with a high degree of constitutional irritation, and with symptoms which bear a striking resemblance to those of typhus fever."—(*On the Diseases of Arteries and Veins, p.* 511, 512.)

The observations of Mr. Arnott tend to show, that the points at which the inflammatory changes in the coats of veins usually terminate, are determined by the passage of a current of blood. Thus, when a trunk is concerned, the boundary is the entrance of a branch; and when a branch is concerned, the boundary is the junction of this with the trunk.—(See *Med. Chir. Trans. vol.* 15, *p.* 47.) It is not meant, however, that the inflammation necessarily stops where a current of blood interferes, but that, at the point where the inflammation does cease, the vein affected either sends off a branch or terminates in a venous trunk.

Besides the example of inflammation of femoral and other large veins, brought on by a ligature round a small aperture accidentally made in the femoral vein in the operation for popliteal aneurism, as mentioned in a foregoing article (*Varicose Veins*), Mr. Travers reports another case, in which a fatal inflammation of the femoral and external iliac veins, with marks of diffused inflammation up to the right auricle, was apparently caused by the application of a ligature to the mouth of the femoral vein, after an amputation.—(*Surgical Essays, p.* 227.) And the same catastrophe would appear to be occasionally the result of venous inflammation after amputation, even where the femoral vein is not tied.—(See *Carmichael, in Trans. of King's and Queen's College of Physicians, vol.* 2, *p* 365.) In short, Mr. Travers's observations, as well as those of Mr. Hodgson and Mr. Carmichael, tend to prove "that the inflammation of the interior tunic of a vein sometimes follows a puncture, sometimes a division, a ligature encircling the tube, or including only a part of it, or arises spontaneously from an inflamed surface, of which the vein forms a part."—(*P.* 238.) Mr. Carmichael relates an instance, in which the appearances after death seemed to evince that the patient died, subsequently to an operation for femoral aneurism, of inflammation and suppuration within the femoral vein, and extending both down the saphena and upwards through the common iliac vein. The femoral vein had been pricked in the operation, but not tied.—(*Trans. of the King's and Queen's College of Physicians, Ireland, vol.* 2, *p.* 350, *&c.*) In order to avoid the danger of wounding the femoral vein above the edge of the sartorius, Mr. Carmichael recommends "introducing the needle on the pubal side of the artery" (*p.* 357); a direction which I have noticed in the article *Aneurism*. With respect to the danger of tying a large vein, Sir A. Cooper is so convinced of it, that he says in his lectures, that if he were the subject of operation, he would rather let his femoral artery be tied than the vena saphena major.

M. Ribes has published one example, in which an inflammation of the veins of the arm arose from a gangrenous chilblain of the hand, and after death, marks of inflammation were traced into the superior vena cava and right auricle and ventricle. He also relates a case of mortification of the foot and leg, and a consequent inflammation of the vena saphena, where appearances of inflammation were also discovered in the right auricle and ventricle, and in the inferior vena cava.—(*Revue Med. Juillet*, 1825.) According to the researches of Mr. Arnott, the extension of inflammation to the venæ cavæ and heart in phlebitis, is a very unusual occurrence, and cannot, therefore, be considered as the cause of death. The suggestion, he observes, which was made by Mr. Hunter, has been adopted without examination. The facts which Mr. Arnott has adduced, tend to prove that there are considerable differences in the extent of vein occupied by inflammation in fatal cases of phlebitis. "Sometimes the disease has spread into several or most of the veins of a limb from that primarily affected; at others, it has not proceeded beyond the vessel in which it originally appeared. This last circumstance, together with that of the fatal consequences sometimes ensuing from inflammation, limited to a few inches only of a vein, justifies the inference that the dangerous consequences from phlebitis bear no direct relation to the extent of the vein which is inflamed."—(*Med. Chir. Trans. vol.* 15, *p.* 44.) In his inquiry into the nature of the connexion between the primary and secondary affections in this disease, Mr. Arnott takes up the question, whether the latter depend upon the secretion of pus by the inflamed vein, and its entrance into the circulation? This leads him to inquire into the contents of the inflamed veins. In several of the cases which he has collected, in which "an open wound existed in the vein, pus was discharged from it during life. While in 14 cases out of 19, pus, or pus in conjunction with lymph, was present in the vessels after death. In two instances no mention is made of pus, the contents of the veins being described in the one, as 'adhesive matter;' in the other, where the vena cava was concerned, as 'flakes of lymph.' In one case only (Mr. Hodgson's), where the inflammation occurred in a vein previously diseased, or in a vein the branches

of which at least were varicose, neither pus nor lymph was found in the vessel.

It results from this statement (says Mr. Arnott), that although pus is present in the veins in the great majority of fatal cases of phlebitis, and that although it appears, from the character of the general symptoms, and the effects produced upon animals by the injection of a similar fluid into their vessels, that the passage of pus into the circulation is probably the principal, yet the circumstances do not justify us in regarding it as the sole cause of the secondary affection. In addition to the presumed absence of pus in two instances, and to its declared absence in a third, it may be remarked that the early appearance of the symptoms in some cases seems scarcely to correspond with the time usually required for the production of pus, as in one which occurred to Mr. Freer (*Hodgson on Dis. of Art. p.* 551), where they came on suddenly, four hours after ligature of the saphena. If, then, the constitutional affection in phlebitis is to be explained by the introduction of a fluid into the circulation which contaminates the blood and operates as a poison, this property must be attributed to inflammatory secretions generally from the vein, although not purulent."—(See *Med. Chir. Trans. vol.* 15, *p.* 45.)

The careful investigations of Mr. Arnott prove that the secondary affection in phlebitis commonly begins in from two to ten or twelve days after the receipt of the injury which has made the vein inflame. The following are described as the symptoms: great restlessness and anxiety, prostration of strength, and depression of spirits, sense of weight at the præcordia, frequent sighing or rather mourning, with paroxysms of oppressed and hurried breathing, the patient being at the same time unable to refer his sufferings to any specific source. The common symptoms of fever are present, the pulse is rapid, reaching sometimes to 130 or 140 in a minute, but is in other respects extremely variable. There is often sickness, with violent vomiting, especially of bilious matter. Frequent and severe rigors almost invariably occur. The general irritability and deep anxiety of countenance increase; the manner is quick; and the look occasionally wild and distracted. When left to himself the patient is apt to mutter incoherently; but on being directly addressed, becomes clear and collected. The features are shrunk, and the skin of the whole body assumes a sallow or yellow colour: under symptoms of increasing debility, and at a time when the local affection may appear to be in a great degree subsiding, secondary inflammation of violent character, and quickly terminating in effusion of pus or lymph, very frequently takes place in situations remote from the original injury; the cellular substance, the joints, and the eye have been affected; but it is more particularly under a rapidly developed attack of inflammation of the viscera of the chest, that the fatal issue usually occurs. Whether this is observed or not, death is always preceded by symptoms of extreme exhaustion, a rapid, feeble pulse, dry, brown, or black tongue, teeth and lips covered with sordes, haggard countenance, low delirium, &c.—(*Arnott, in Med. Chir. Trans. vol.* 15, *p.* 52.)

This gentleman considers the resemblance of the secondary affection in phlebitis to the diseases arising from the inoculation of a morbid poison, as particularly striking; and the conclusion to which his facts and arguments bring him is, that death, in cases of phlebitis, does not take place from the inflammation extending to the heart, but that the entrance of pus or even of some other product of inflammation, from the inflamed part of the vein into the circulation, is the source of the alarming and fatal indisposition.—(*Op. cit. p.* 61.)

The formation of abscesses in the liver, joints, lungs, &c. after injuries of the head, parturition, great surgical operations, and suppurating wounds (see *Velpeau, in Revue Méd. Juin, Juillet, et Dec.* 1826; *Mai*, 1827; *Rose, in Med. Chir. Trans. vol.* 14), is also referred by Mr. Arnott to inflammation of the veins of the part primarily affected, and the entrance of pus into the circulation; and (says he) it becomes a question, whether the occurrence of phlebitis and the passage of pus from an inflamed vein into the circulation, are not sufficient of themselves to account for the secondary affections of wounds, without its being necessary to resort to an absorption of the same fluid from their suppurating surfaces.—(See *Med. Chir. Trans. vol.* 15, *p.* 68—122, *&c.*)

The researches of Mr. Arnott on this interesting subject certainly reflect great credit upon his industry and judgment; and if they do not altogether free particular points from doubt, they certainly present the most rational views of them, which have hitherto been given.

Inflammation frequently produces a thickening of the coats of the veins, as well as adhesion of their sides and obliteration of their cavities. Indeed, in some instances, these vessels have been found to resemble arteries in the thickness of their coats, and in retaining a circular form when cut across.—(*Hodgson, op. cit. p.* 513.)

Ulceration sometimes extends to the coats of veins, and by exposing their cavities gives rise to hemorrhage. In certain examples, it commences in the membranous lining, and destroys the other coats. In general, however, the adhesive inflammation precedes the ulcerative, and by obliterating the cavities of these vessels, prevents the occurrence of hemorrhage. When sphacelation takes place in the vicinity of veins, their cavities, like those of arteries under similar circumstances, are filled with extensive plugs of coagulum, which prevent hemorrhage upon the separation of the mortified part.

Veins are sometimes ruptured without any previous morbid alteration in their structure, and the accident may be induced by muscular exertions, external violence, the sudden effects of the cold bath, &c.

Although a deposition of calcareous matter almost invariably takes place in the arteries of persons advanced in life, it is an extremely rare occurrence in the coats of veins.

Loose calculi have been found in the cavities of veins; and tumours sometimes grow from their lining. In a case of scirrhous pylorus, Mr. Hodgson found a tumour larger than a hazel nut, growing from the lining of the splenic vein, and resembling in its appearance and consistence the disease which existed at the pylorus.—(*P.* 524.)

The venous, like the arterial, system appears to be capable of carrying on a collateral circulation, when any part of it is impervious. Even after the obliteration of the vena cava inferior, the blood has been known to be conveyed with facility to the heart through the lumbar veins and vena azygos. In the case recorded by Dr. Baillie (*Trans. for the Improvement of Medical and Chir. Knowledge, vol.* 1, *p.* 127), it is remarkable, that the vena inferior was obliterated at the point where the venæ cavæ hepaticæ opened into it, so that not only the blood from the lower extremities, but also that from the liver, must have passed through collateral channels to the heart.

Want of room having prevented me from introducing farther observations on the diseases of veins, I must refer to the following works for additional information. *J. Hunter, in Trans. for the Improvement of Med. and Chir. Knowledge, vol.* 1, 1793. *Abernethy's Works, vol.* 2. *J. Hodgson, on the Diseases of Arteries and Veins. Longuet, Dis. sur l'Inflammation des Veines, Paris*, 1815. *B. Travers, in Surgical Essays, part* 1, 8*vo. Lond.* 1818. *F. A. B. Puchelt, Das Venensystem in Seinen Krankhaften Verhältnissen*, 8*vo. Leipz.* 1818. *R. Carmichael, in Trans. of the Association of Fellows, &c. of the King's and Queen's College of Physicians in Ireland, vol.* 2, 8*vo. Dublin*, 1818. *J. M. Arnott, A Pathological Inquiry into the Secondary Effects of Inflammation of Veins, in Med. Chir. Trans. vol.* 15.

[A valuable paper on the "Surgical Anatomy of the Veins," by Professor Annan, of Washington Medical College, Baltimore, will be found in the Maryland Medical Recorder, vol. 1, No. 2. I regret that my limits preclude me from inserting even a portion of it, as it contains much valuable matter of a practical kind, and on a subject too much overlooked by surgical writers. —*Reese.*]

VENEREAL DISEASE. (*Lues Venerea. Morbus Gallicus. Syphilis.*) About the year 1494, or 1495, the venereal disease is said to have made its first appearance in Europe. Some writers believe, that it originally broke out at the siege of Naples; but most of them suppose that, as Columbus returned from his first expedition to the West Indies, on March 13th, 1493, his followers brought the disorder with them from the new to the old world. Other authors, however, among whom are Mr. Beckett (*Phil. Trans. vols.* 30 *and* 31), Mr. B. Bell, and Dr. Swediaur, maintain the opinion, that the venereal disease was well known upon the

old continent, and that it prevailed among the Jews, Greeks, and Romans, and their descendants, long before the discovery of America. Another doctrine, not entirely destitute of ingenious arguments, and even containing many valuable truths, is, that the venereal disease, as it is considered in modern times, has no real existence as a distinct affection, arising from any particular virus, but is a name given to an assemblage of disorders of different kinds, to which the human race have always been subjected from time immemorial.—(See a tract entitled "*Sur la Non-existence de la Maladie Vénérienne*," *8vo. Paris*, 1811.) One writer of high reputation believes, that though syphilis was brought to Europe by the followers of Columbus, there existed previously to that event throughout the old continent venereal disorders, both local and constitutional, which strongly resembled the newly-imported disease, and were for more than three centuries confounded with it.—(*R. Carmichael on Venereal Diseases*, *p.* 33, *8vo. Lond.* 1825, *ed.* 2.) My friend Mr. Bacot has bestowed great pains on an examination of all the passages in old works, affording any ground for the opinion that syphilis existed in ancient times: he finds in them allusions to many local complaints of the genitals, warts, discharges, ulcers, pustules, &c., sometimes clearly ascribed to impure coition, but no distinct reference to any constitutional symptoms. "Surely," says he, "I may be allowed to say, that if there is any historical fact that can be said to be proved, it is that of the origin of syphilis being referable to the latter years of the fifteenth century; for, I cannot understand otherwise, why, at that precise period, we all at once hear of ulcers on the parts of generation in both sexes, followed speedily by excruciating nocturnal pains, by corroding ulcers over the whole body, by affections of the throat and nose, and very frequently by death; when not one word that can be construed into any similar affection is to be met with distinctly stated by any writer before that period."—(*J. Bacot, in Med. Gazette*, *vol.* 2, *p.* 100.) But while this writer will not admit the truth of the existence of the venereal disease in times of antiquity, he allows that a disorder resembling gonorrhœa has been known from the remotest periods of history.

Although many considerations lead me to coincide with Hunter, Sprengel, Pearson, and Bacot, in rejecting the common history of syphilis as fabulous, I mean that account which refers its origin to America, or the French army in Italy, it does not appear to me that any utility would be likely to result from agitating this question in modern times, because, if it be true, as the most candid and intelligent surgeons of the present day generally acknowledge, that they cannot precisely define what the venereal disease is, nor always point out the exact circumstances in which it differs from some other anomalous complaints, even when the cases are before their eyes, how can such discrimination be attempted from a mere review of old descriptions, not accompanied with the advantage of a view of the living patients themselves? But as far as the nature of the venereal disease has been unravelled, and it is allowable to judge from such comparisons, I may be permitted to remark, that, in degree of severity, acuteness of symptoms, rapidity of propagation, and extent and quickness of fatality, no forms of disease, now ever conjectured to be venereal, bear the least resemblance to the destructive malady with which the army before Naples was afflicted at the close of the fifteenth century: nor will any ignorance of the uses of mercury, as will be presently noticed, explain differences so strongly marked. With reference to the contagious disorder which scourged a great part of Europe at the close of the fifteenth century, there is a decree of the parliament of Paris, dated 1496, in which the disease is mentioned to have been then prevalent in that city two years: consequently it was known there in 1494: yet the conquest of Naples by Charles the VIII. was not effected till 1495. It is clear, therefore, that the disease here alluded to, could not have been derived from America. It appears to have been communicated from one person to another by the mere touch, residence in the same chamber, &c.; and, in fact, unless some other mode of propagation besides coition be supposed, its extension throughout Europe in two years, would imply a depravity of manners quite extraordinary, and beyond all credibility. Another fact is, that whatever the disorder might be, it was not of long continuance; and Guicciardini, the historian, who wrote a few years after its breaking out, assures us, that it had already become much milder, and undergone of itself, a change into kinds different from the first.

The venereal disease is supposed to arise from a specific morbid poison, which, when applied to the human body, has the power of propagating or multiplying itself, and is capable of acting both locally and constitutionally.

Mr. Hunter was of opinion, that the effects produced by the poison arise from its peculiar or specific irritation, joined with the aptness of the living principle to be irritated by such a cause, and the parts so irritated acting accordingly. Hence he considered that the venereal virus irritated the living parts in a manner peculiar to itself, and produced an inflammation peculiar to that irritation, from which a matter is produced peculiar to the inflammation.

The venereal poison is capable of affecting the human body in two different ways: locally, that is, in those parts only to which it is first applied; and constitutionally, that is, in consequence of its absorption.

In whatever manner the venereal disease was first produced, it began, says Mr. Hunter, in the human race, as no other animal seems capable of being affected by it. He conceives also, that the parts of generation were those first affected; for if the disease had taken place on any other part, it would not have gone farther than the person in whom it first arose. On the contrary, if the disease, in the first instance of its formation, be presumed to have attacked the parts of generation, where the only natural connexion takes place between one human being and another, except that between the mother and child, it was in the most favourable situation for being propagated; and Mr. Hunter infers, also, that the first effects of the disease must have been local, in consequence of the fact, now well established, that none of the constitutional effects are communicable to other persons, that is to say, infectious.

Thus, the numberless cases of the venereal disease, afflicting generation after generation, and observable in all the known parts of the world, are supposed to be originally derived from the amours of some unfortunate individual, in whom the poison was first formed, from causes beyond the reach of human investigation. But that any statement of this kind is more valuable than unsupported conjecture, is a proposition to which my mind is not prepared to assent, particularly when it is considered, that sores on the genitals, giving rise to such constitutional symptoms as puzzle the most discerning practitioners, are often of a very diversified character, so as hardly to admit of reference to one common origin. And, as I have already hinted, every modern speculation about the origin of the distemper, promises but little instruction or success, because the question relates to a disease, the diagnosis of which is still very unsettled, and the complete definition of which has hitherto baffled men of the greatest genius and experience.

According to Mr. Hunter, the venereal poison is commonly in the form of pus, or some other secretion. In most cases it excites an inflammation which (to use the same author's language) is attended with a specific mode of action, different from all other actions attending inflammation, and accounting for the specific quality in the matter.

The formation of matter, though a general, is not a constant, attendant on this disease; for inflammation produced by the venereal poison, sometimes does not terminate in suppuration. But if Mr. Hunter's sentiments are correct, it is the matter produced, whether with or without inflammation, which alone contains the poison. Hence, a person having the venereal irritation in any form not attended with a discharge, cannot communicate the disease to another. In proof of this doctrine he states, that though married men often contract the disease, and continue to cohabit with their wives, even for weeks, yet, in the whole of his practice, he never once found that the complaint was communicated under such circumstances, except when connexion had been continued after the appearance of the discharge.

The late Mr. Hey, of Leeds, however, gave it as his opinion, that a man might communicate lues venerea after all the symptoms of the disease had been removed, and he was apparently in perfect health.—(See

Med. Chir. Trans. vol. 7, p. 547.) This sentiment is not only repugnant to the authority of Mr. Hunter, but to common observation and all sound reasoning. The very case which Mr. Hey adduced in proof of the occurrence, is decidedly inadequate to the purpose, in consequence of the impossibility of trusting to the accounts which patients, under circumstances involving their honour, are apt to give of themselves. In the case recited by him, the patient might have had some venereal affection at the period of, or subsequently to, his marriage; and yet his feelings, and a sense of the disgrace of infecting a virtuous woman, might have compelled him to conceal the real truth from his surgeon. Again, it is to be remembered, that the lady herself might have deviated from the path of chastity, and exposed herself to infection; and, if she had done so, she would have informed neither her husband nor Mr. Hey. I confess that it is at all times painful to suspect the veracity of individuals whose situations in life are respectable; but whenever an occurrence takes place decidedly contrary to the evidence of general experience, every possibility is to be recollected, in order to avoid the necessity of admitting doctrines not founded upon truth.

Mr. Hey, with much more reason, joins in the belief of the possibility of the venereal disease being communicated to the fœtus in utero, though in what manner the infection is transmitted, is a question not yet elucidated. A universal desquamation of the cuticle; a hoarse, squeaking voice; copper-coloured blotches; a scaly eruption upon the chin; an unnatural redness of the anus; are the common symptoms which he sets down as proofs of syphilis in very young infants. As these complaints yield to small doses of the submuriate of mercury, or the hydrargyrus cum creta, and either the nurse or parent has had some venereal or syphiloid disease at no very distant period, the cases are often regarded as decided specimens of one of these disorders.

The venereal poison would appear to be very irregular in its effects, different persons being variously affected by it; and hence, probably, one cause of a great deal of the uncertainty yet prevailing about its distinguishing characters. Thus, as Mr. Hunter mentions, two men sometimes have connexion with the same woman; both catch the disease; but one may have very severe, the other exceedingly mild symptoms. He knew of an instance, in which one man gave the disease to different women, some of whom had it with great severity, while the others suffered but slightly. On the same point I find an interesting statement, made by Dr. Hennen, in his *Report of Observations on Syphilis in the Military Hospitals in Scotland*:—"We have had (says he) frequent opportunities of remarking two or more sores of different kinds, existing at the same time: an irregularly-shaped, diffused sore; an elevated sore, covered with a light-coloured slough, as if a bit of chamois leather had been stuck on by some tenacious substance; a groove or streak along the glans, as if made by a scraping instrument, filled with purulent matter; and the true and perfect chancre, according to Mr. Hunter's definition; or the true syphilitic ulcer, according to Mr. Carmichael. This last has, in some cases, occupied the glans; in some the prepuce; while the sores of another description have been on the same part close beside it, or on another part at a distance. Three of these cases I particularly selected for examination and public demonstration, at the Castle Hospital; in one, the Hunterian chancre was on the glans, and a sore without any hardness on the prepuce; in another, it was on the prepuce, and a simple ulcer on the glans; in the third, a most perfect specimen of Hunterian chancre occupied the internal prepuce close to the corona glandis; and, at about half an inch from it, nearer the frænum, but farther from the glans, was an elevated ulcer. In all these cases, the Hunterian chancre healed (without mercury) several days before the others.

"Soldiers (says Dr. Hennen) are gregarious in their amours, and we have frequently several men at the same time in hospital infected by the same woman, with whom they have had connexion in very rapid succession; *some of them have had one kind of sore, some another, and some both.*—(*Principles of Military Surgery, ed. 2, p. 525.*) But if these facts, which agree with my own observations, be rather adverse to the theory of a plurality of venereal poisons (see *Carmichael's Essays on the Venereal Disease, &c.*), they still leave difficulties which cannot be entirely solved by reference to peculiarities of constitution and different states of the health, because no explanation on this principle would account for a man having, at the same time, upon the penis, two or three different kinds of ulcers, apparently excited by one cause. Neither will any difference of texture afford the needed explanation, though the utmost latitude be given to the doctrine, that the appearance and progress of sores are considerably modified by the nature of the parts. It is only necessary to consider the above passage from Dr. Hennen's work, to perceive that the particular texture, whether prepuce, skin, glans, or corona glandis, does not always communicate to sores one invariable character, even when they arise, as the evidence would dispose one to suppose, as nearly as possible under the same circumstances, and from the same source of infection.

But though in such examples no data with which I am acquainted lead to any safe inference, respecting the exact cause of the diversity of effect produced in different persons, and even on different parts of the same individual by one kind of virus, not a doubt can be entertained, that generally climate and constitution have vast influence over the venereal disease. In all warm countries, the disorder, as far as regards the natives, and those who have been long settled there, is not only much milder in its symptoms, but much more easy of cure. In the West Indies, the Brazils, &c., it has for a long period of time been very commonly cured by means of sarsaparilla, guaiacum, mezereon, &c., without a grain of mercury. It is alleged, however, that this mildness of syphilitic complaints, and their facility of cure in warm climates, do not extend to strangers recently arrived there, who are said even to suffer more from the virulence of the disease than in their native climate. In Portugal, during the late war, the dreadful ravages of the venereal disease among the British soldiers, and its comparatively milder phenomena among the inhabitants of the country, were particularly noticed. "In the British army (says Dr. Fergusson), it is probable that more men have sustained the most melancholy of all mutilations, during the four years that it has been in Portugal, through the disease, than the registers of all the hospitals in England could produce for the last century; while venereal ulceration has not only been more intractable to the operation of mercury than under similar circumstances at home, but the constitution, while strongly under the influence of the remedy, has become affected with the secondary symptoms in a proportion that could not have been expected. With the natives, on the contrary, the disease is very mild; curable, for the most part, by topical treatment alone, or wearing itself out when received into the constitution, after running a certain course, not always a very destructive one, without the use of any adequate mercurial remedy, &c. The bulk of the people, and of all the military at the hospitals, even though a general order has been given out enjoining the use of mercury, cure themselves or get cured by other means. I have now been upwards of two years at the head of their hospital department, and I can declare, that it never occurred to me among all the venereal patients whom in that time I have seen pass through the hospitals, to meet a single one under the influence of mercury, excepting those cases wherein I myself have personally superintended its administration. They go out cured by topical remedies alone; and I have lived long enough among them to ascertain that their return to hospital under such circumstances for secondary symptoms, is far from being a universal or even a frequent occurrence."—(*Fergusson, in Med. and Chir. Trans. vol. 4, p. 1, 2.*)

The inference at which Dr. Fergusson arrives is, that, in Portugal, the disease is exhausted, and has lost much of its virulence, in the same manner as the natural small-pox, unresisted by inoculation, appears to have changed, in the same country, into a very mild disease, which does well under any mode of treatment.

"Yet (says Dr. Fergusson) I have no doubt, that were this mild disease, or the mildest that was ever produced from the improved inoculation of England, communicated to a tribe of Indians, or to a plantation of negroes, or any other class of people who had never before known the small-pox, it would desolate with all

the fury of pestilence, destroying wherever it could find victims, and never ceasing until it had destroyed the whole." And, on the same principles, Dr. Fergusson attempts to explain the severe effects of the inoculation of the exhausted syphilitic virus of Portugal into the constitution of the British or other stranger, and the impossibility of curing the disease by the same treatment which answers for the natives themselves.—(*Med. Chir. Trans. vol.* 4, *p.* 7. 10.) On the other hand, Mr. Guthrie does not admit, that the disease which the troops contracted in Portugal was more violent than the same complaint in England; or rather, he admits the fact, but gives a different explanation of it from that of Dr. Fergusson; and refers the severe effect of the disease upon the soldiers in Portugal to the operation of the climate upon their northern constitutions, and their irregularity and intemperance, vices to which the natives are not addicted.—(See *Med. Chir. Trans. vol.* 8, *p.* 563.)

The opinion, that the venereal disease was continually changing in its nature, and that, in the end, it would entirely cease, is one that has been brought forward at various periods ever since its supposed importation into Europe. Von Hutten would lead us to suppose, that its original violence did not last more than about seven years from the assumed period of its birth: "*qui nunc vagatur fœditate tolerabilior qui nunc grassatur vix illius generis esse putetur.*" J. Benedictus also writes: "*tempore isto, non reperiuntur gallicantes cum tam sævis accidentibus sicut apparuerunt ante aliquot annos.*—(*De Morb. Gallico, cap.* 3, *anno* 1508.) The idea that syphilis would at some period be extinguished, is as ancient as the times of Fracastorius:

Cum fata dabunt labentibus annis
Tempus erit, cum nocte atra sopita jacebit interritu data.

From the testimony of these and other writers, especially that of A. T. Petronius (*lib.* 1, *cap.* 3) and B. Tomitani (*lib.* 2), no doubt can be entertained, that the severe, rapidly spreading, and frequently fatal disease, which broke out in Italy at the close of the fifteenth century, did not continue many years with its original violence, but changed so much as even to justify the opinion, defended by many able men, that it was a totally different disorder from any complaint now reputed to be venereal. And the historical fact of the gradual change in the nature of the disease which broke out in the French army before Naples, at the close of the fifteenth century, might be taken as an argument against its having been syphilis, by those who will not admit that the latter disease has undergone any alteration of character. Among the moderns, Peyrilhe has denied the correctness of the doctrine, that the nature of the venereal disease is changed: he treats of two sorts of change or degeneration, as it was termed; one general; the other particular. He denies the first, and maintains that the venereal disease is as destructive now as in past times. As for the degeneration of the poison in an individual, he admits it: "perhaps (says he) *spontaneous cures* will be doubted: *numerous facts attest them* to those who know how to see, and we have tried to demonstrate them to others. For our own part, we cannot doubt that the venereal poison becomes weaker and weaker in the infected person, becomes milder, and, as it gets older, loses its principal character, its property of communicating the disease."—(See *Remède Nouveau, &c. Montp.* 1786.)

It has been a contested question, whether the venereal disease and gonorrhœa arise from the same poison? Mr. Hunter acknowledges, that the opinion of their originating from two distinct poisons seems to have some foundation, when the difference in the symptoms and method of cure is considered. But he asserts, that if this question be taken up upon other grounds, and experiments be made, the result of which can be safely depended upon, this notion will be found to be erroneous. As the arguments of Mr. Hunter, in support of the doctrine, that both diseases are produced by the same virus, are noticed in the article *Gonorrhœa*, I shall not here repeat them.

On the other hand, Mr. B. Bell relates some experiments, from which the conclusion is made, that the poisons of the venereal disease and gonorrhœa are entirely different and distinct.

Matter was taken upon the point of a probe from a chancre on the glans penis, before any application was made to it, and completely introduced into the urethra. For the first eight days, the gentleman who made this experiment felt no kind of uneasiness; but about this period he was attacked with pain in making water. On dilating the urethra as much as possible, nearly the whole of a large chancre was discovered, and in a few days a bubo formed in each groin. No discharge took place from the urethra during the whole course of the disease; but another chancre was soon perceived in the opposite side of the urethra, and red precipitate was applied to it as well as to the other, by means of a probe previously moistened for the purpose. Mercurial ointment was at the same time rubbed on the outside of each thigh, by which a profuse salivation was excited. The buboes, which, till then, had continued to increase, became stationary, and at last disappeared entirely; the chancres became clean, and, by a due continuance of mercury, a complete cure was at last obtained. If this case, and another to which I shall presently advert, could be entirely depended upon, they would tend to disprove the part of Mr. Hunter's theory, accounting for the different effects of the same poison by its application in the case of chancre to a non-secreting surface covered with cuticle, and that of gonorrhœa to a secreting mucous membrane. However this may be, I have never seen a chancre within the urethra.

The next experiment was made with the matter of gonorrhœa, a portion of which was introduced between the prepuce and glans, and allowed to remain there without being disturbed. In the course of the second day, a slight degree of inflammation was produced, succeeded by a discharge of matter, which, in the course of two or three days, disappeared.

The same experiment was repeated; but no chancre ever ensued from it.

Two medical students were anxious to ascertain the point in question; and with this view they made the following experiments, at a time when neither of them had ever laboured under either gonorrhœa or syphilis, and both in these and in the preceding experiments, the matter of infection was taken from patients who had never made use of mercury.

A small dossil of lint, soaked in the matter of gonorrhœa, was by each of them inserted between the prepuce and the glans, and allowed to remain on the same spot for the space of twenty-four hours. From this it was expected that chancres would be produced; but in one a very severe degree of inflammation ensued over the whole glans and præputium, giving all the appearance of what is usually termed *gonorrhœa spuria*. A considerable quantity of fetid matter was discharged from the surface of the inflamed parts, and for several days there was reason to fear that an operation would be necessary for the removal of a paraphymosis. By the use of saturnine poultices, laxatives, and low diet, however, the inflammation abated, the discharge ceased, no chancre took place, and the case got entirely well. In the other gentleman, says Mr. B. Bell, the external inflammation was slight, but in consequence of the matter finding access to the urethra, he was attacked, on the second day, with a severe gonorrhœa, with which he was troubled for more than a year.

The next experiment was made by the friend of the latter student: he inserted the matter of gonorrhœa, with a lancet, beneath the skin of the præputium, and likewise into the substance of the glans; but, although this was repeated three different times, no chancres ensued. A slight degree of inflammation was excited; but it soon disappeared, without any thing being done for it. His last experiment was attended with more serious consequences. The matter of a chancre was inserted on the point of a probe to the depth of a quarter of an inch or more, in the urethra. No symptoms of gonorrhœa ensued; but, in the course of five or six days, a painful inflammatory chancre was perceived on the spot to which the matter was applied. To this succeeded a bubo, which ended in suppuration, notwithstanding the immediate application of mercury; and the sore that was produced proved both painful and tedious. Ulcers were at last perceived in the throat, nor was a cure obtained till a very large quantity of mercury had been given, and the patient kept in close confinement for thirteen weeks.—(*On Gonorrhœa Virulenta and Lues Venerea, vol.* 1, *ed.* 2, *p.* 438.

&c.) Mr. Evans, it appears, has also several times inoculated with the matter of gonorrhœa, but, *in every case*, it *failed* to produce any effect.—(*On Ulceration of the Genital Organs*, *p.* 81, 8*vo. Lond.* 1819.)

Some other facts on record, however, tend rather to support Mr. Hunter's inference, if any conclusion can be ventured upon without the aid of the most minute details. Thus Vigaroux mentions an instance in which six young Frenchmen had connexion with the same woman, one after the other. The first and fourth, in the order of connexion, had chancres and buboes, the second and third gonorrhœa, the fifth chancre, and the sixth bubo.—(*Œuvres. de Chir. Pratique; Montp.* 1812, *p.* 8.) And Dr. Hennen, who refers to this case, mentions a similar one, in which the first person escaped, the second had true chancres and elevated sores, and the third gonorrhœa. The connexion took place within an hour.—(*Military Surgery, edit.* 2, *p.* 526.) These facts would indeed be much more interesting, if the disease with which the women were affected had been ascertained, and one could securely calculate upon the men not having exposed themselves within a given time to any other sources of infection. In short, without a perfect history and description of cases of this kind, from their beginning to their end, no light is thrown by them on the question about the venereal and gonorrhœal poisons. Nor does Dr. Hennen quote them with this view; but for the purpose of exemplifying the variety of effects produced on different individuals *apparently* by the same infection; though the same consideration which prevents any certain inference from such observations, in regard to the identity of the venereal and gonorrhœal poisons, seems also to interfere with the other conclusion. In the experiments detailed both by Hunter and B. Bell, there is also one point assumed by both parties, though it is far from being determined, viz. that the matter discharged from the urethra is always of one kind, in respect to its infectious principle, whatever this may be, and that the secretion from every chancre contains one, and only one, species of infectious matter. From the candid and very practical work of Mr. Evans, it would appear that some ulcerations on the penis, such as would usually be called chancres, though they have of late years been sometimes named elevated ulcers, *arise from an altered secretion, without any breach of surface, or discernible disease in the female organs.* The same gentleman was also frequently present at the examinations of the public women in Valenciennes, and always surprised at the small portion of disease to be found among them: "At one which I attended (says he), no less than 200 women of the lowest description, and, of course, the most frequented by soldiers, were examined, and *not one* case of disease was found among them: nevertheless the military hospitals had, and continued to have, their *usual number* of venereal cases (ulcerations).

At an inspection I have since attended, where 100 women were examined, *only two* were found with ulcerations: I noticed several with increased secretions, and one with purulent discharge, but these were taken no notice of by the attending surgeons, as they did not come sufficiently under the head of virulent gonorrhœa.

That the *two women* above mentioned as having ulcers, infected the whole of the men diseased in garrison, during the preceding fifteen days, no one can for a moment admit even as likely; but if it be allowed that an altered secretion be sufficient for the production of this disease (the ulcus elevatum), we shall at once have an explanation of how it happened that the military hospitals continued to have their usual number of venereal cases, &c."—(*Evans on Ulcerations of the Genital Organs*, *p.* 72, 73, *&c.*) From the investigations of the same author, the ulcus elevatum is the most frequent of all the sores met with on the genitals, and besides being excited by diseased secretions and gonorrhœal matter, is *capable of being transferred by inoculation*, and even of originating spontaneously. —(*P.* 67—81, *&c.*)

Lagneau admits that gonorrhœa may not always proceed from the same poison as the venereal disease; but he believes that in the greater number of instances, the virus is of the same quality. He is led to this opinion by the consideration of several women having been infected by the same man with *both* complaints, and of the two diseases having been communicated to several men who had cohabited with one woman, and *as is presumed with her alone*, at least inasmuch as may relate to the possibility of any other infection weakening the conclusion attempted to be drawn from the case; a point which has only been assumed, and by no means ascertained. However, be this and other similar narrations true or not, in every particular, I agree with Mr. Guthrie in believing that the evidence adduced on the point under consideration, justifies the opinion "that ulcers will arise on the penis from the matter of gonorrhœa; that gonorrhœa will in its turn be caused by the matter of these same ulcers; and that both occur in consequence of promiscuous or uncleanly intercourse. *That many of the ulcers produced in this manner will occasionally assume every character of chancre, and cannot be distinguished from it*, I am perfectly satisfied of from repeated observation; but I am equally certain, that a gonorrhœa in men, with the worst appearances and symptoms, can, and often does arise from irritating causes common to parts free from any specific disease or poison, is not distinguishable from one that has arisen from promiscuous intercourse, and that both complaints are curable in the same way, and without mercury." On the question, whether gonorrhœa or the ulcers resulting from the matter of gonorrhœa, can produce constitutional symptoms, Mr. Guthrie believes that they generally do not, although he does not affirm that they cannot under particular circumstances of constitution; and he is farther of opinion, that if such symptoms ever really arise, they become serious only in consequence of the exhibition of mercury.—(See *Med. Chir. Trans. vol.* 8, *p.* 554.) Delpech considers the possibility of a general infection from the effect of what he terms a *syphilitic* gonorrhœa, completely proved; though he admits that there are numerous instances in which this consequence does not happen. He owns that the distinction of one class of cases from the other is, *à priori*, extremely difficult, and most frequently quite impossible. Yet, widely dissenting from established modern practice, he inclines to ancient maxims, and considers it prudent to destroy the first effect of the infection without delay, his aim being to shorten the duration of the discharge with cubebs, or copaiba, and then to introduce mercury into the system through the same channel as conveys the virus into it, by rubbing the ointment on the integuments of the penis.—(*Chir. Clinique*, *p.* 292.)

From what has been already observed, it must be evident, that one of the greatest obstacles to our arrival at a satisfactory knowledge of the nature of lues venerea, is the fact, that under this denomination, many various diseases are comprised and confounded, and the particular distinctions of each of which are not yet sufficiently made out to enable surgeons to form a well-founded and practical classification of them, satisfactory to every impartial observer, and agreeing with general experience. But though such progress has not yet been made, the attention of modern practitioners, and especially that of John Hunter, Mr. Abernethy, and Mr. Carmichael, has been directed to the subject. In fact, notwithstanding some mysterious circumstances in particular syphilitic cases may not admit of complete and satisfactory explanation by the doctrine of a plurality of poisons, no intelligent surgeons, I believe, now suppose that the diseases frequently communicated by sexual intercourse always proceed from one peculiar poison. As Mr. Rose has observed, long before syphilis is supposed to have commenced its career in the world, some of these diseases were frequently met with, and Mr. Pearson thinks that in addition to those formerly known, new forms of disease have occasionally arisen, "which are succeeded by a regular series of symptoms nearly resembling the progress of lues venerea."—(*Obs. on the Effects of various Articles of the Materia Medica in the Cure of Lues Venerea*, *2d ed. Introd. p.* 53; *and Rose in Med. Chir. Trans. vol.* 8, *p.* 418.) Mr. Hunter also, in the seventh chapter of his Treatise on the Venereal Disease, speaks of many examples of new-formed diseases, arising from peculiar poisons, quite different, he supposes, from every other virus previously known, or judged of by its effects. But though Mr. Rose appears to join in the belief of a plurality of poisons, he is very far from considering it settled, how far the variety in the symptoms of venereal cases is to be attributed to different poisons, or how far the symptoms of the same

poison may be modified and altered by constitution, climate, and habits of life. He remarks, that we seldom have an opportunity of tracing different cases to the same source of infection, and of comparing their progress with each other.—(*Vol. cit. p.* 419.) And I may add, that as far as observations of this nature have been made, and can be trusted, they rather tend to prove, as already noticed in the foregoing columns, that different individuals, when infected nearly at the same time and by the same woman, are very far from having any uniformity in their complaints; some having one kind of sore, some another, and others claps, &c. And the tenor of the remarks made likewise by Mr. Evans, as far as he has yet entered into the subject, lead equally to the conclusion, that one primary complaint, when it produces another, does not always occasion one resembling itself. Thus, the ulcus elevatum on the penis, though capable of being communicated by inoculation, appeared sometimes to be the effect of one kind of infection, sometimes of another, and sometimes even to have a spontaneous origin. Who shall unravel all these intricacies I know not, whether he bring to his assistance plurality of poisons, or states of the parts and constitution, climate, neglect, intemperance, wrong treatment, or any other circumstance, which can possibly be conceived to have influence over the appearances, progress, and consequences of the disease. Nay, it would appear from some of the curious and perplexing histories mentioned in the preceding pages, that one kind of primary complaint in an individual may impart to other persons primary complaints of a different nature, so that even the hope of elucidating parts of this abstruse subject, by adverting to a plurality of infections, and a vigilant observation of their characteristic effects, meets with discouragement almost at its very birth; and though the doctrine of several kinds of poisons being concerned in the production of syphilis and syphiloid diseases still maintains its ground, an absolute proof of its correctness can hardly be said to have been yet afforded; nor indeed could it be obtained, unless the inoculation of healthy individuals with the matter of the different forms of disease were justifiable for the elucidation of the question. And, as this is not the case, I think, with Mr. Carmichael, that it might be a benefit to society if criminals were sometimes permitted to commute a heavier punishment by submitting to such experiments, without which the inquiry into the reality, number, nature, and effects of the morbid poisons under consideration, can perhaps never be brought to a satisfactory termination. "I am perfectly aware (says Mr. Carmichael) how much the state of the human constitution will modify local diseases, and am willing to attribute to a certain extent, the great variety of appearances we witness daily in venereal complaints, to this cause alone. But we observe that many of those primary ulcers evince, from their very commencement, such peculiar and distinct characters, that it would be quite an absurdity to believe that the virus is always the same, and the variety of characters dependent alone upon constitution. Thus, nothing can be more opposite, from the commencement, than the common chancre, with its hardened base, like a piece of cartilage under the skin, and the sloughing ulcer. The first is slow and chronic; the latter begins with a mortified spot, extends by alternate sloughing and phagedenic ulceration, and makes more progress in three days, than the former in as many weeks.

The phagedenic ulcer is equally distinct from chancre, as it does not evince at any period a hardened base, but gradually creeps from one part to another of the penis, leaving those parts to heal which in the first instance it attacked; so that when the disease has existed for some months, the glans is seen to exhibit its entire surface furrowed over with ulcerations and cicatrices.

There is a raised ulcer, also, with elevated edges, approaching the nature of the phagedenic ulcer, yet whose characters are sufficiently distinct to be considered as a separate species. But the most common venereal primary ulceration presents such various appearances in different individuals, that, until a more exact knowledge is obtained, it is better described by its negative than its positive qualities, and it may be designated an ulcer without induration, raised edges, or phagedenic surface.

If (continues Mr. Carmichael) the plurality of venereal poisons is supported by the variety of primary ulcers, it is equally so by the multiplicity of constitutional eruptions. A primary ulcer, which was not phagedenic or sloughing at first, may afterward, like any other ulcer, become so by irritation, neglect, or inflammation. But I do not conceive that we have grounds for supposing that the state of the constitution can so modify morbid poisons, as to cause the same virus to produce in one person the chronic scaly lepra and psoriasis, and to assume in another a decided pustular form, each pustule spreading rapidly into a deep ulcer."—(*On the Symptoms and specific Distinctions of Venereal Diseases, p.* 6, *&c. 8vo. Lond.* 1818.)

The same gentleman, in his Essays on this subject, published some years previously to the above date, gives his reasons for believing that certain primary appearances are followed by a corresponding train of constitutional symptoms. 1st, That the syphilitic chancre gives rise to scaly eruptions, lepra, and psoriasis, an excavated ulcer of the tonsils, and pains and nodes of the bones. 2dly, That the ulcer, without induration, raised edges, or phagedenic surface, gonorrhœa virulenta, an excoriation of the glans and prepuce, are followed by a papular eruption, which ends in desquamation, pains in the joints resembling those of rheumatism, soreness of the fauces, and frequently swelling of the lymphatic glands of the neck, but without any nodes of the bones. 3dly, That the ulcer with elevated edges, in the few instances in which it was traced by Mr. Carmichael to its constitutional symptoms, was followed by a pustular eruption, which terminated in mild ulcers, pains in the joints, and ulcers in the throat, but no appearance of nodes. 4thly, That the phagedenic and sloughing ulcers are generally attended with constitutional symptoms of peculiar obstinacy and malignity; viz. pustular spots and tubercles, which form ulcers, generally spreading with a phagedenic edge, and healing from the centre. Extensive ulceration of the fauces, particularly of the back of the phaynrx, obstinate pains of the knees and other joints, while nodes are frequently present, and the bones of the nose are occasionally affected.—(See *Carmichael's Essays, and his Obs. on the Symptoms, &c. of Ven. Diseases, p.* 9.)

The observations of other modern writers seem generally to coincide with those of Mr. Carmichael respecting the great variety of character in primary venereal sores, and partly also with regard to the hypothesis of various kinds of poisons or infectious matter. But on some other great questions immediately connected with these points, little similarity of opinion prevails between him and other gentlemen, who have laudably and impartially entered into the disquisition. And, in the first place, without adverting again to certain statements already premised, which render it probable that differences of the virus, or, at all events, differences in the forms of the primary complaints in the contaminating individuals, would not always explain the reason of the diversified appearances and nature of the primary forms of disease in the contaminated, I shall lay before the reader other evidence having an immediate relation to Mr. Carmichael's sentiment, that each kind of primary venereal sore is followed by a peculiar and corresponding train of constitutional symptoms. In the cases recited by Mr. Rose, "most of the papular eruptions followed ulcers which were not very deep, and which healed without much difficulty. Several of them had a thickened, but not a particularly indurated margin. This corresponds with the observations of Mr. Carmichael:—*I could not, however, discover any decidedly uniform character in such sores*; and the 16th case I should have considered as a well-marked instance of chancre."—(*Med. Chir. Trans. vol.* 8, *p.* 399.) In another place, it is stated that the appearances of sores can seldom be relied on in parts of such vascular structure, and in the midst of sebaceous glands.—(*P.* 419.) With respect to the phagedenic ulcer, Mr. Rose expresses his belief that it is rarely followed by secondary symptoms, though he inclines to the opinion that it arises from the application of some morbific matter, acknowledging, however, the great difficulty of deciding "whether the great degree of erethismus, excited by the local affection, should be attributed to any peculiarity in that matter, or is owing to the peculiar state of the constitution."—(*Med. Chir. Trans. vol.* 8, *p.* 372.) And he then refers to the case reported by Dr Fergusson, where

"the infection was communicated by an opera dancer at Lisbon, apparently in perfect health, who continued on the stage for several months afterward, occasionally infecting others, without any thing extraordinary, as far as he could learn, in the nature of the symptoms."—(*Op. cit. vol.* 4, *p.* 12.) And, on the same subject, Mr. Guthrie does not think "that Mr. Carmichael's opinion, as to the secondary symptoms peculiar to the phagedenic and sloughing ulcer, receives any support from what occurred to the troops in Portugal; because it did not appear that either of them, following sexual intercourse, were dependent on the cause which produced the ulcer. Where many men have had intercourse with the same woman (and with no others?), they have not all had the same complaint, although one of the ulcers so originating has become hagedenic or sloughed; neither has the same woman herself suffered from this distemper; indeed, the nature of an ulcer of either kind must, after a short time, effectually prevent any intercourse; and we often find that their peculiar characters only appear after the ulcer has existed for several days. I firmly believe, also, that in the greater number of cases of sloughing ulcer, *where mercury is not given, no secondary symptoms would appear;* and in those cases in which they did appear, I apprehend they would be equally dependent on the state of the constitution, as to the mode of cure and their destructive characters. In other words, my observations lead me to conclude that *these ulcers do not depend upon a specific poison*, but *on the state of the constitution* under particular excitement; and that *when secondary symptoms occur, they are not dependent on the state of the ulcer;* although I am ready to admit, that in a constitution where an ulcer will readily become phagedenic, the secondary symptoms, when they occur, may be different to a certain extent from those that follow more simple ulcers in a healthier habit of body."—(*Guthrie, in Med. Chir. Trans. vol.* 8, *p.* 564.) My observations lead me to believe, with Mr. Guthrie, that primary *sloughing* ulcers do not depend upon any peculiar poison; and I am also disposed to join him in the opinion, that when hurtful local treatment is out of the question, they are chiefly owing to the state of the constitution. According to my experience, all kinds of ulcers on the genitals may, from particularity of constitution, impairment of health, and sometimes from the pernicious effects of the immoderate and indiscriminate employment of mercury, assume in their progress a sloughing disposition, and even have it from their very commencement. Mr. Rose mentions a case, in which a *healthy* young man was affected with a sloughing sore on the penis, in consequence of a suspicious connexion. It was not attended with any constitutional disturbance, and yielded readily to mercury. The same patient, twice afterward, at a very considerable interval, had a fresh infection, and the sores each time had precisely the same character as the first. This, says Mr. Rose, is no uncommon occurrence, and it is not probable that the sloughing and appearance of the sores arose from the peculiarity of the poison.—(*Med. Chir. Trans. vol.* 8, *p.* 420.) And another intelligent and experienced surgeon, who has particularly attended to this investigation, declares his conviction that "many varieties of sore, independently of the sloughy chancre mentioned by Mr. Carmichael, lead to constitutional symptoms, differing in no respect from those he has described, and admitting of the same mode of cure." Nor does he believe, with Mr. Carmichael, that only one particular species of sore is capable of producing the true secondary symptoms of lues.—(*J. Bacot, On Syphilis, p.* 51.)

From these observations, I think we may safely infer, that with respect to the *sloughing ulcer*, it neither arises from the application of any one specific poison to the part, nor is it connected with any regular train of secondary symptoms.

Dr. Hennen assures us, that he has frequently had occasion to observe that eruptions of the same nature and character have succeeded to the foul, indurated, excavated ulcer, and to the simple excoriation. "In fifteen cases of eruptions, unaccompanied by any other symptoms, which succeeded the Hunterian sore, six were tubercular, five exanthematous, two pustular, one tubercular and scaly, and one tubercular and vesicular.

In four cases following the same sore, but in which the eruptions were complicated with sore throat, two were tubercular, one was tubercular and scaly, and one was tubercular and exanthematous.

In twelve cases following the *non* Hunterian sore, and in which eruptions were the only symptoms, six were pustular, three were exanthematous, and one was tubercular and scaly.

In seven cases where the eruption was accompanied with sore throat, three were exanthematous, two were tubercular, one was papular, scaly, and tubercular, and one was pustular and tubercular." Dr. Hennen also recites an instance, in which a Hunterian chancre was, at the distance of ten weeks, succeeded by a *papular eruption*, which, in the course of a month, was removed by low diet, purgatives, and the decoction of sarsaparilla. In two months afterward, an eruption of a similar nature appeared without any fresh infection. This was treated with mercury, which was administered five weeks, so as to excite a moderate salivation. Under this treatment the eruption faded, having during its progress assumed the appearance of *vesicles* and *pustules*, and at length falling off in amber-coloured *scales* with livid bases. Notwithstanding this mercurial course, the patient was a third time admitted, ten weeks afterward (without any intervening primary affection), with a *pustular* eruption, which was finally cured without mercury, and the pustules falling off in squamulæ. In another month, without any fresh infection, he was a fourth time taken into hospital with a very thickly dispersed *pustular* eruption, somewhat different from the former, the pustules being more numerous, smaller, and acuminated. They yielded to non-mercurial treatment. During all these attacks, there was aphthous sore throat, and occasional flying pains in the joints. The inference drawn from this case is, that even a full and judiciously conducted mercurial course does not prevent the reappearance of venereal eruptions, and that they assume at different times different characters, notwithstanding the interruption they receive in their natural progress by the use of that remedy.—(*On Military Surgery, ed.* 2, *p.* 528—530.) After these accounts, I can have no hesitation in coming to another conclusion, which is, that with the exception of the partial confirmation of Mr. Carmichael's doctrine by Mr. Rose, as far as relates to the frequency of papular eruptions after superficial primary ulcers, the regular connexion of particular forms, of secondary symptoms with any given descriptions of primary sores, is so far from being supported by the testimony of other observers, that one kind of primary ulcer may lead in the same patient to eruptions of several different sorts, either existing together on various parts of the body, or breaking out in succession; and no regular connexion can be traced between any one species of primary sore and any determinate class of secondary symptoms. These truths, I believe, must be admitted, disadvantageous as they are to the prospect of bringing the diagnosis of syphilis to a final settlement, so as to enable the writer to describe the disease with accuracy, and the practitioner to recognise and treat it with certainty. The first essential step to the elucidation of this subject, however, is undoubtedly the subversion of every doctrine relative to it, which is repugnant to general experience. The same facts which may render it necessary for Mr. Carmichael to retract some of his inferences, and which have now been established beyond all doubt or possibility of successful contradiction by the very impartial, disinterested, and extensive investigations made in the army hospitals, would have obliged even Hunter himself, had he been alive, to confess the mistaken views which he sometimes took of the nature of the venereal disease.

With respect to Mr. Carmichael's theory, Mr. Bacot has brought forwards several arguments against it. "Mr. Carmichael (he says) gives us an example of a phagedenic sore, followed by those appearances which should attach to the raised ulcer; he admits that the papular and pustular diseases are sometimes mixed; in some of his phagedenic cases we find that that character has been given to the ulcer by the action of mercury; in still more of them the original character of the sore is not preserved throughout, so that the form of secondary symptoms, which ought to succeed to the classification, is very difficult to divine; in short, he frequently departs from his own arrangement. His description of a phagedenic ulcer includes, unless I am much mistaken, two very distinct kinds of sore; and,

in more than one instance, a phagedenic surface and elevated edges are united in the same description of ulcer. Nay, more; he tells us, that occasional difficulty is encountered in distinguishing the phagedenic ulcer from the other primary ulcers. It displays, however, its character of phagedena so early, that, he thinks, it cannot often be confounded with an ulcer that becomes phagedenic from irritation; and, he adds, that neglect, local irritation, and even constitutional irritability will cause any ulcer to become phagedenic. What then should prevent me from assuming, that an early irritation may produce an early change in the character of the sore? And then what becomes of the phagedenic ulcer, and its appropriate, consecutive, constitutional symptoms?"—(*J. Bacot, in Med. Gazette, vol.* 2, *p.* 422.) Notwithstanding this reasoning, however, if it were proved that the primary phagedenic ulcer, not made so by irritation, neglect, &c. always, or even generally, were followed by one kind of secondary symptoms and not by others, Mr. Carmichael's researches would have contributed much to enlighten this obscure subject. As I do not believe, that sores, which are originally phagedenic, necessarily depend upon any one peculiar virus, of course much difficulty presents itself to my mind in the adoption of this part of Mr. Carmichael's views.

In a very ingenious paper by Mr. Welbank I find several observations well deserving the attention of the practical surgeon. Among other things, he suggests a plan of investigating venereal diseases, which, if carefully followed up, might throw considerable light on their diagnosis. "Instead of recording with laboured minuteness the resemblance or dissimilarity, confessedly sometimes fallacious, of primary sores, of eruptions, or of other really or seemingly consecutive diseases in the cases of *different individuals*, we should (says he) faithfully chronicle the diversity of disease existing at the same time in the same person. We should note, for instance, the various character and progress of a phagedenic sore, as it attacks different tissues, or the phenomena of several of these sores, when they have occurred at the same time, in different situations, from the same infection. Let us also record the multiform secondary effects of the same disease, contemporaneous in their appearance or coexistent in the same system, and various as they are manifested in absorbents, mucous membrane, skin, cellular tissue, fibrous membrane, or in the bones. From repeated observation of collective phenomena, we shall soon arrive at the inference, that many affections, often noticed in conjunction, but various in their apparent characters, are in reality the constant result of one or other distinct stimulus, acting upon a diversity of organization. By a patient and unbiassed prosecution of this mode of inquiry, we cannot fail soon to acquire diagnostic data, which will enable us to solve some of the most difficult problems in the distinction of venereal complaints."—(*Med. Chir. Trans. vol.* 13, *p.* 566.) Mr. Welbank's experience leads him to admit the general truth of Mr. Carmichael's opinions, of which he recommends a farther patient investigation. He also endeavours to obviate some of the difficulties which occur in their adoption.

Were it granted (he observes) that syphilis had arisen in the same individual, together with the venereolic ulcer, under the same circumstances of infection, rather than reason generally from such an exception, or adopt so unphilosophical a conclusion, as that one and the same cause, acting under precisely the same circumstances, could produce effects so distinctly different as venerola and chancre; the one disease being directly amenable to mercury, and the other often exasperated by its use; it would be safer to suppose, that the virus of syphilis had coexisted in the infected person." He refers to various instances of sores resulting from connexion with women apparently healthy; venerola, phagedena, &c. A point noticed by him as not sufficiently adverted to in considering the multiplicity of disease, apparently arising from the same infection, is the disposition which may exist in different or the same individuals to spontaneous morbid affections of the genitals, and consequently not unlikely to succeed the mere local excitement of sexual intercourse. Among these he specifies the psoriasis præputii and scrotalis, in which may frequently be observed distinct spots of a brownish tint and elevated. These, he says, are often scaly, and with them may exist similar spots about the scalp and upper extremities. In some instances, erythematous and aphthous inflammations of the tonsils, fauces, and mouth take place, and sometimes repeated discharges from the urethra, generally of short duration. Mr. Welbank considers one source of the great variety in the effects of morbid poisons to be the various degree of power, which is ascertained by direct experiments to be proportionate to the temporary activity of the disease from which the contagious matter is taken. On this various degree of virulence, he conceives, the circumstance may depend, whether an eruption in the same texture of the skin shall be papular, vesicular, or pustular, or a phagedenic sore be deep or superficial, stationary or disposed to extend its ravages. Another source of complexity in the multiform phenomena of the same poison lies, according to Mr. Welbank, in many adventitious circumstances influencing the character of primary venereal sores by their stimulant or sedative effect. The occasional coexistence of distinct primary diseases, he sets down as the possible origin of much complexity in the secondary phenomena.—(See *Med. Chir. Trans. vol.* 13, *p.* 578, *&c.*) Many of these circumstances are of course only suggested as possibilities, to which farther attention should be directed.

Among other doctrines, Mr. Hunter inculcates, that "the venereal matter, when taken into the constitution, produces an irritation which is capable of being continued, independent of a continuance of absorption, *and the constitution has no power of relief;* therefore *a lues venerea continues to increase.*" The same criterion was proposed by Mr. Abernethy, who states, that the "constitutional symptoms of the venereal disease are generally progressive, and never disappear, unless medicine be employed."—(*Surgical Observations, p.* 137.) And notwithstanding some dissent may be traced in both old and modern writers, from the belief that mercury was absolutely essential to the cure of the venereal disease, and an opposite conclusion might easily have been drawn from the whole history of this subject, including the practice of former and present times, the contrary hypothesis was that always taught in all the great medical schools of this country, even down to so late a period as fifteen years ago. But the error no longer prevails; and no facts are more completely established, than that mercury, however useful it may frequently be in the treatment of the venereal disease, is not absolutely necessary for the cure either of the primary or secondary symptoms; and that the disease, so far from always growing worse unless mercury be administered, ultimately gets well without the aid of this or any other medicine. If any man yet doubt the general truth of this statement, let him impartially consider the many facts and arguments brought forwards in proof of it in the anonymous tract "*Sur la non-existence de la Maladie Vénérienne,*" and in the writings of Dr. Fergusson, Mr. Rose, Dr. Hennen, Dr. Thomson, Mr. Guthrie, Mr. Bacot, and other modern practitioners. Perilhe, as I have already noticed, distinctly admitted the frequency of spontaneous cures, and so does Delpech. "Observation seems to prove (says he), that there are some individuals, in whom the lymphatic system appears to be endued with the fortunate property of extinguishing the syphilitic principle, so that merely primary symptoms occur."—(*Chir. Chimique, t.* 1, *p.* 341.) In short, if there be such a skeptic now living in this country, let him peruse the returns made by the surgeons of the whole British army, documents which will be noticed in the sequel of this article; let him consider the evidence of the surgeons of other countries, especially that of Cullerier, who annually demonstrates to his class of pupils the cure of venereal ulcers without mercury; and the testimony and practice of the German surgeons who were attached, during the war, to regiments of their countrymen in the British service. The fact is therefore indisputable, that the venereal disease, in all its ordinary and diversified forms, is capable of a spontaneous cure, and, consequently, that the question, whether the disease is syphilitic or not, can never be determined by the circumstance of the complaint yielding, and being permanently cured, without the aid of mercury. Yet, as Mr. Rose has observed, the supposition, that syphilis did not admit of a natural cure, and that mercury was the only remedy that had the power of destroying its virus, was of late so much relied upon, that where a disease had been cured without the use of that medicine, and did not afterwaid return

such fact alone, whatever might have been the symptoms, was regarded as sufficient proof that it was not a case of syphilis. And, as the same writer very judiciously remarks, the refutation of these notions is of considerable importance, "not so much in reference to the treatment of syphilis, under common circumstances, for the strikingly good effects of mercury will probably not render it advisable in general to give up the use of that remedy, but from *the change it will produce in our views of the diagnosis of the disease.* The distinction which has engaged such a share of attention of late years, and which is evidently so important between syphilis and syphiloid diseases, has been made to depend so much on the former admitting of no cure, except by mercury, that, if this principle should be found to be erroneous, the difficulties which have attended it will in a great measure be explained."—(*Med. Chir. Trans. vol.* 8, *p.* 350, 351.) That it is erroneous, will appear more clearly when the treatment of syphilis falls under consideration.

Excluding from present attention works of ancient date, it is curious to find how very near several writers, within the last twenty or thirty years, arrived at the same point to which recent investigations have led. Thus Mr. B. Bell observes, that "a chancre might frequently be cured with external applications alone, and as we know from experience that the virus is not always absorbed, *the cure would in a few instances prove permanent;* but as we can never with certainty know whether this would happen or not, while, in a great proportion of cases, there would be reason to think that absorption would take place, we ought not in any case to trust to it."—(*On Gonorrhœa Virulenta, &c. vol.* 2, *ed.* 2, *p.* 325, 8*vo. Edinb.* 1797.) And, in some reflections upon a case of doubtful nature, Dr. Clutterbuck long ago remarked: "Supposing even that the diseased appearances had after a time got well of themselves, *I should deem even this no absolute proof of their not being of a venereal nature.* I have seen cases which induce me to believe, that *the venereal disease,* in some of its stages and in certain circumstances, *may get well without mercury or any other remedy.* But this is contrary to the doctrine of Mr. Hunter, who supposed that venereal actions go on increasing, without any tendency to wear themselves out. That lues venerea is much modified by climate and other circumstances is generally allowed; that it has been cured by other means than mercury, we have also very sufficient evidence in the older writers on the subject; not to mention the late successful trials with acids and other substances. *Many of the appearances on the skin go off spontaneously.* When purple spots appear on the skin (Mr. Hunter observes, *p.* 319), giving it a mottled appearance in this disease, many of the spots disappear, while others continue and increase."—(*H. Clutterbuck, Remarks on some of the Opinions of the late Mr. John Hunter, p.* 27, 8*vo. Lond.* 1799.) If Dr. Clutterbuck had advanced one step farther, and declared that the venereal disease might be cured without mercury or any other remedy in all, or nearly all, its forms, and not merely in some of them, he would actually have anticipated the most important fact, recently established chiefly by the meritorious labours of the army surgeons, whose opportunities of going through the investigation were better on several accounts than those of private practitioners, who generally soon lose sight of their patients, and never have them sufficiently under their control and observation to render a full perseverance in any method a matter of certainty. At all events, Dr. Clutterbuck may justly claim the merit of having distinctly marked the fact, that *the circumstance of a disease giving way, and being cured without mercury, is no proof that the case is not venereal.*

One of the most ingenious theories ever devised for explaining all the perplexities and irregularities of syphilis, is unquestionably that of the late Mr. Hunter; for it accommodated itself almost to every thing, and every believer in it fancied he could account satisfactorily for many puzzling occurrences, which admitted of no good explanation on other principles. Mr. Hunter inculcated, that the parts contaminated by the absorption of the venereal poison, do not immediately begin to be palpably diseased, but only acquire *a disposition to take on the venereal action.* He farther believed, that when this *disposition* was once formed in a part, it necessarily changed into *action,* or manifest disease, at some future period. That mercury can cure the disease, when positively formed, but not the *disposition* to it. That although mercury cannot destroy the *disposition* already contracted, yet that it can prevent it from being formed at all. That the *disposition* never becomes the real disease, or, in Mr. Hunter's language, goes into action during the use of mercury. That the action, having once taken place, always increases, never wearing itself out. That parts once cured never become again contaminated from the same stock of infection. And that the matter of secondary ulcers, or those which break out in consequence of absorption, is not infectious. What Mr. Hunter meant by the term *disposition,* I think is better explained, than the grounds for the adoption of the theories connected with it: viz. the presumption of its being formed in all the parts, capable of contamination; the certainty of its future change into actual disease; the impossibility of curing it by mercury, previously to such change; but the possibility of preventing its formation at all by the timely use of that remedy.

Dr. Clutterbuck has well observed, that the only foundation for all these hypotheses, connected with the phrase *disposition,* is the fact that *secondary symptoms sometimes arise, notwithstanding a full use of mercury.* If, says this gentleman, we were to suppose, with Mr. Hunter, that all the parts which are susceptible, become at once contaminated, and mercury has no influence over them in this state, the constitution should become affected in almost all cases; for absorption probably always precedes the application of remedies. Either, therefore, mercury does prevent the future action, or a more frequent absence of susceptibility to the disease must be supposed, than there are grounds for imagining.—(*Remarks on the Opinions of Mr. Hunter, p.* 9—12.) But surgeons of the present day, enlightened by many new facts unequivocally determined since Mr. Hunter's time, know very well, that a *disposition* to the disease is in many instances not produced at all, even though the matter of a chancre be supposed to be absorbed; since in a large proportion of cases of chancres, which had all the characteristic appearances of such ulcers, according to Mr. Hunter's own description, no secondary symptoms followed, though the patients were treated and cured without any mercury. Yet, if Mr. Hunter's theory were true, the disposition must have been produced, the action or disease itself, in the form of secondary symptoms, must have ensued, sooner or later, and no cure could have been ultimately effected without mercury. Fortunately for mankind, unsound as some of the theories seem, which are attached by Mr. Hunter to the supposed *disposition of the venereal disease,* or its latent form, there was one piece of advice given by him, which may be said to have had a beneficial effect in practice, though founded upon these very doctrines; and it was this: "that we should push our medicine no farther than the cure of the visible effects of the poison, and allow whatever parts may be contaminated to come into action afterward."—(*On the Venereal Disease, p.* 334.) This maxim, I know, has been regarded by some admirers of long salivations, as the cause of many relapses and imperfect cures; but when I advert to the dreadful mischief which formerly attended protracted courses of mercury for latent and imaginary complaints, my mind regrets that Mr. Hunter himself should not have strictly adhered in practice to his own principle, from which he undoubtedly deviated with his patients, and even in certain other parts of his writings. However, the effect has been to discourage long courses of mercury; and perhaps in this way the world has been benefited by the counsel, though not rigorously adopted by him who gave it. Confessing my own inability to reconcile the various theories about the nature and effects of the venereal poison, to many facts which are disclosed in practice, I shall now proceed to offer a few remarks on each of the primary and secondary symptoms.

Chancres.—The penis, as Mr. Hunter has observed, which in men is the common seat of a chancre, is, like every other part of the body, liable to diseases of the ulcerative kind, and, on some accounts, is rather more so than other parts. When attention is not paid to cleanliness, excoriations or superficial ulcers often originate. The genitals, also, like almost every other part that has been injured, when once they have suffered from the venereal disease, are very liable to ulcerate

again. Since, therefore, the penis is not exempted from common diseases, every judgment of the nature of ulcers upon it, as Mr. Hunter truly remarks, should be formed with great attention, particularly as all diseases upon this part are suspected to be venereal. But for a particular description of the many ordinary complaints which are apt to occur on the genitals, either preceded or unpreceded by sexual intercourse, I refer to Mr. Evans's treatise.—(See *Pathological and Practical Remarks on Ulcerations of the Genital Organs*, 8*vo. Lond.* 1819.) From the facts already mentioned in this article, however, it would appear, that primary syphilitic ulcers, or chancres, by which I imply sores capable of giving rise to the secondary symptoms of the venereal disease, have no determinate external character, are extremely diversified in their appearance, and absolutely cannot be distinguished by their mere look from sores which are of a common or, at least, a very different nature. This is another important fact, for which every man in the profession who seeks only truth, and the expulsion of errors from the doctrines of surgery, must feel obliged to the army surgeons. Nor is their merit lessened by the consideration, that the detection of mistake on this point, like the discovery of the error concerning the invariable progress of the venereal disease from bad to worse, unless medicine be given, has taken place in opposition to the tenets of Mr. Hunter.—"*Venereal ulcers* (says he) *commonly have one character*, which, however, is not entirely peculiar to them; for many sores that have no disposition to heal (*which is the case with a chancre*) have so far the same character. *A chancre has commonly a thickened base*, and, although in some the common inflammation spreads much farther, yet the specific is confined to this base."—(*P.* 215.) And elsewhere, he observes, a chancre first begins with an itching in the part. When the inflammation is on the glans penis, a small pimple, full of matter, generally arises, without much hardness, or seeming inflammation, and with very little tumefaction; for the glans penis is not so apt to swell in consequence of inflammation as many other parts are, especially the prepuce. Mr. Hunter also explains, that chancres situated on the glans are not attended with so much pain and inconvenience as sores of this nature on the prepuce. When chancres occur on the frænum, or particularly on the prepuce, a much more considerable degree of inflammation soon follows, attended with effects more extensive and visible. These latter parts, being composed of very loose cellular membrane, afford a ready passage for the extravasated fluids. The itching is gradually converted into pain: in some cases, the surface of the prepuce is excoriated, and afterward ulcerates; while in other examples a small pimple or abscess appears on the glans, and then turns into an ulcer. *The parts become affected with a thickening, which at first, while of the true venereal kind, is very circumscribed*, not diffusing itself, as Mr. Hunter observes, gradually and imperceptibly into the surrounding parts; but *terminating rather abruptly. Its base is hard, and the edges a little prominent.* When it begins on the frænum, or near it, that part is very commonly wholly destroyed, or a hole is often made through it by ulceration. Mr. Hunter thought it better in general, under the latter circumstance, to divide the part at once.

When the venereal matter is applied to the body of the penis, or front of the scrotum, where the cuticle is thicker than that of the glans penis and prepuce, the chancre generally makes its appearance in the form of a pimple, which commonly forms a scab, in consequence of evaporation. The first scab is generally rubbed off; after which, a second still larger one is produced.

When the disease is more advanced, it is often attended with inflammation peculiar to the habit, becoming in many instances more diffused, and often producing phymosis and paraphymosis. However, says Mr. Hunter, *there is yet a hardness around the sores, which is peculiar to such as are caused by the venereal virus*, particularly those on the prepuce

Mr. Carmichael, also, in his arrangement of primary ulcers on the penis, considers the true chancre as being particularly distinguished by its hardened base, which he compares to a piece of cartilage under the skin. It is to be observed, however, that, by the true chancre, or primary syphilitic ulcer, he does not signify that it is the only sore from which secondary symptoms may arise; but his observations lead him to regard it as the cause of such constitutional effects as belong to what he deems the true form of syphilis, or that in which the use of mercury is the most decidedly indicated. It would give me sincere pleasure to find any agreement on this part of the subject among other observers. The reader, indeed, must already know, that the hardened base, which both Hunter and Carmichael have regarded as a distinguishing character of a true chancre, is not found to be so by other gentlemen, who have most impartially investigated this point. Thus Dr. Hennen observes, "We are not in possession of the knowledge of any invariable characteristic symptoms, by which to discriminate the real nature of the primary sore, and we are equally at a loss in many of the secondary symptoms. I am well aware, that some practitioners have assumed to themselves the possession of a 'tactus eruditus,' by which they can at once distinguish a chancre, or a venereal ulcer, or eruption, in which mercury is indispensable, from one of a different nature; but I have seen too many instances of self-deception to give them all the credit that they lay claim to. It would be by no means difficult to show, that the high round edge, the scooped or excavated sore, the preceding pimple, the loss of substance, *the hardened base and edge, whether circumscribed or diffused*, and the tenaciously adhesive discharge of a very fetid odour, are all observable in certain states and varieties of sores, unconnected with a venereal origin. The hardened edge and base, particularly, can be produced artificially by the application of escharotics to the glans or penis of a sound person, and if any ulceration or warty excrescence previously exists on these parts, this effect is still more easily produced."—(*On Military Surgery, ed.* 2, *p.* 517.) Now, if it be asked, whether the chancre with a hardened base and prominent edge is distinguished by its not admitting of cure without mercury, and by any regularity or peculiarity in the nature of secondary symptoms, when they originate from such an ulcer? modern experience denies the validity of both these criteria. If Mr. Rose's excellent paper be consulted, the reader will see that this gentleman has certainly cured, without the aid of mercury, ulcers which had a decidedly marked induration of the margins and bases, by which the syphilitic chancre, according to Mr. Carmichael, is easily distinguished.—(*Med. Chir. Trans. vol.* 8, *p.* 421, *&c.*; also, *Guthrie, vol. cit. p.* 576.) And as for the other points, sufficient evidence has already been detailed in the foregoing columns to satisfy any impartial mind, that, as far as the eye can teach us, no kind of primary sore has yet been satisfactorily proved to be the cause of only one set of peculiar constitutional symptoms; but on the contrary, that a great variety of appearances in the skin, throat, &c. may follow sores which, as far as external characters are concerned, seem exactly alike. The only partial exception to this remark is, the great frequency of papular eruptions after superficial sores: a point on which both Mr. Carmichael and Mr. Rose agree, though the latter gentleman does not represent even this connexion as constant. Mr. Hunter computed that claps appear more frequently than chancres, in the proportion of four or five to one: I am not prepared to offer any opinion on this calculation, in reference either to chancres as defined by that interesting writer, or under the more comprehensive view of them to which the results of modern investigations would lead. One intelligent writer, however, has observed, that present experience does not justify Mr. Hunter's conclusion respecting the infrequency of chancre compared with gonorrhœa.—(*J. Bacot, Obs. on Syphilis, p.* 54.) Yet in Dublin, if Mr. Carmichael's statement be correct, the frequency of gonorrhœa, as compared with that of what is sometimes termed the true venereal chancre, must be so great as to defy all computation; for he informs us, that since the descriptions of the success of the non-mercurial practice fell into his hands, he has been anxious to ascertain, by personal observation, whether true syphilitic chancres did really admit of being cured without mercury; but, says he, "this disease, as described by Hunter, has diminished in so extraordinary a degree in this country, that, strange to say, I have from that period met with only one case of true chancre."—(*Observations on the Symptoms, &c. of Venereal Diseases, p.* 14.) As this chancre remained stationary a month, it was thought proper to employ mercurial frictions, and it then soon healed.

leaving a callosity which continued two months longer. However, after the above passage was written, Mr. Carmichael met with two cases of "well-marked chancre," each of which was attended with psorias syphilitica, scaly from its commencement. No mercury was given. For five weeks the disease gained ground; but in the end, both cases were cured, merely by the administration of sarsaparilla. The following observations, contained in the appendix to Mr. Carmichael's work, do him infinite credit: "Although (says he) these two cases cannot fail to make a due impression, yet, if they stood alone, their evidence could not be deemed sufficient to establish a belief, that true syphilis, like the papular disease, is capable of yielding to the powers of the constitution or to remedies in which mercury does not form an ingredient. But this deficiency seems to be in a great measure supplied by the testimony of Mr. Rose, Dr. Hennen, and other equally intelligent surgeons, who had the advantage of serving with our army on the continent; and if, in the preceding pages, I appear to be skeptical, with respect to the accuracy of their observations, and doubted that it was true chancre and true syphilitic eruption which yielded to their prescriptions unaided by mercury, these two cases have satisfied me, that every attention is due to the exactness and discernment of these respectable individuals; and if I hesitated until I saw with my own eyes, and judged with my own understanding, I claim for my own observations no larger a measure of faith from others." And he afterward adds, "In thus relinquishing my opinion that true syphilis differs from other venereal complaints by always requiring mercury for its cure, it is necessary to reduce the doctrine I hold to this proposition: that, with respect to the use of that medicine, it differs from them only in not being injured, but decidedly benefited by it in all its symptoms and stages.—(*P.* 218, 219.)

According to Mr. Hunter, there are three ways in which chancres may be produced: first, by the poison being inserted into a wound; secondly, by being applied to a non-secreting surface; and thirdly, by being applied to a common sore. A wound, it seems, is much more readily infected than a sore. To whichever of these three different surfaces the pus is applied, it produces its specific inflammation and ulceration, attended with a secretion of pus. The matter produced in consequence of these different modes of application, he says, partakes of the same nature as the matter which was applied; because, he observes, the irritations are alike. How the alleged examples of very different primary sores being sometimes communicated by the application of the matter of chancre, are to be reconciled with the Hunterian doctrines, it is difficult to suggest, unless Mr. Carmichael's observation about the present excessive rarity of the true syphilitic chancre can furnish the explanation. However, as far as I can believe my own eyes and judgment, I now see in London the same forms of chancre which used to prevail during my apprenticeship at St. Bartholomew's Hospital, more than twenty years ago. And if any difference can be particularized, it is only that which depends upon their being less rarely converted into worse diseases than mere syphilitic ulceration, by the dreadful effects of immoderate courses of mercury.

With respect to the three modes in which Mr. Hunter speaks of the venereal poison being applied and taking effect, I know not why he should have altogether excluded secreting surfaces; for of this nature (as a late writer remarks) are the glans penis and corona glandis (*Bacot on Syphilis*, *p.* 55); and of a similar kind are the insides of the labia, the surfaces of the nymphæ, &c., where sores are common enough. Whatever may be the truth of the impossibility of the formation of chancres within the urethra, the latter considerations certainly tend to prove that the secreting nature of its membrane is not the only reason for the alleged fact.

I shall not here detain the reader with descriptions of the primary ulcer with elevated edges, the phagedenic, and the sloughing chancre. Such descriptions I have imbodied in the last edition of the First Lines of Surgery, with the sentiments of Mr. Carmichael respecting the train of constitutional symptoms, appertaining, as he believes, to each form of ulcer. It is an interesting disquisition; but as far as my observations and inquiries go, it has not yet reached any degree of certainty or precision; and, as I have already explained, the reports published by other gentlemen engaged in this investigation, do not by any means confirm the much-desired intelligence, that such progress has been made in the knowledge of all the diversified symptoms of the venereal disease, that its varieties can now be classed, both in regard to the primary ulcers and the secondary symptoms connected with each description of chancre.

I firmly believe, that with respect to all the appearances of this disease, both in its primary and secondary forms, a vast deal depends upon constitution, independently of the nature of the virus. And I adopt this opinion, at the same time that many reflections already hinted at in this article lead me to join in the belief, that syphilitic diseases may depend upon a variety of poisons, whereby some of the perplexity of these cases may be explained.

The local or immediate effects of the venereal disease are seldom wholly specific; but are usually attended both with the specific and constitutional inflammation. Hence, Mr. Hunter advises particular attention to be paid to the manner in which a chancre first appears, and to its progress. If the inflammation spreads in a quick and considerable way, the constitution must be more disposed to inflammation than natural. When the pain is severe, Mr. Hunter remarks, there is a strong disposition to irritation. Chancres also, sometimes, soon begin to slough, there being a strong tendency to mortification. Here he probably adverts to what are now usually called phagedenic sores, and frequently believed to differ from the truly venereal chancre.

It is also observed by Mr. Hunter, that when there is a considerable loss of substance, either from sloughing or ulceration, a profuse bleeding is no uncommon circumstance, more especially when the ulcer is on the glans. The adhesive inflammation does not appear to take place sufficiently to unite the veins of this part of the penis, so as to prevent their cavity from being exposed, and the blood escapes from the corpus spongiosum urethræ. The ulcers or sloughs often extend as deeply as the corpus cavernosum penis, and similar bleedings are the consequence.

With respect to chancres in women, the labia and nymphæ, like the glans penis in men, are subject to ulceration, and the ulcerations are generally more numerous in females than males, in consequence of the surface on which the sores are liable to form being much larger. As Mr. Hunter observes, chancres are occasionally situated on the edge of the labia; sometimes on the outside of these parts; and even on the perinæum. When the sores are formed on the inside of the labia or nymphæ, they can never dry or scab; but when they are externally situated, the matter may dry on them, and produce a scab, just as happens with respect to chancres situated on the scrotum or body of the penis.

Mr. Hunter remarks, that the venereal matter from these sores is apt to run down the perinæum to the anus, and excoriate the parts, especially about the anus, where the skin is thin, and where chancres may be thus occasioned.

Chancres have been noticed in the vagina; but Mr. Hunter suspected that they were not original ones, but that they had spread to this situation from the inside of the labia.

Before any of the virus has been taken up by the absorbents and conveyed into the circulation, a chancre is entirely a local affection. From the Hunterian doctrines, however, it would appear, that absorption must generally soon follow the occurrence of the sore; and all the modern opinions concerning the nature of ulceration itself, would lead to the same inference. When no secondary symptoms take place after the cure of chancre without mercury, I believe few surgeons of the present day would attempt to account for the fact by the hypothesis of the matter not having been absorbed; and this observation is made, with every disposition on my part to express my assent to the truth of another circumstance, viz. that some persons appear much more susceptible of the effects of the venereal disease than other individuals. It is remarked by Mr. Hunter, that the interval between the application of the poison, and its effects upon the parts, is uncertain; but that, on the whole, a chancre is longer in appearing than a gonorrhœa. However, the nature of the parts affected makes some difference

When a chancre occurs on the frænum or at the ter mination of the prepuce in the glans, the disease in general comes on earlier; these parts being more easily affected than either the glans penis, common skin of this organ, or the scrotum. He adds, that in some cases in which both the glans and prepuce were contaminated from the same application of the poison, the chancre made its appearance earlier on the latter part. Mr. Hunter knew of some instances in which chancres appeared twenty-four hours after the application of the matter; and others, in which an interval of seven weeks, and even two months elapsed, between the time of contamination and that when the chancre commenced. However, here, as in almost all other statements about this perplexing subject, we never know with certainty that the writer has sufficient grounds for the assumed fact, that it is only one kind of poison which is spoken of.

It was one of Mr. Hunter's opinions, that the ulceration arising from venereal inflammation generally, if not always, continues till cured by art; and his theoretical reason for this circumstance was, that, as the inflammation in the chancre spreads, it is always attacking new ground, so as to produce a succession of irritations, and hinder the disease from curing itself.

It was, no doubt, the foregoing opinion of Mr. Hunter, which formed the authority for the position which was always forcibly insisted upon in the surgical lectures of Mr. Abernethy, which I attended many years ago, viz. that all truly venereal complaints, when not counteracted by remedies, invariably grow progressively worse, which is not the case with pseudo-syphilitic diseases. But modern experience apprizes us that this doctrine is far from being correct. As I have noticed in the foregoing pages, Dr. Fergusson assures us that, in Portugal, the disease in its primary state among the natives is curable without mercury, and by simple topical treatment; that the antisyphilitic woods, combined with sudorifics, are an adequate remedy for constitutional symptoms; and that the virulence of the disease has there been so much mitigated, that, after running a certain course (commonly a mild one) through the respective orders of parts, according to the known laws of its progress, *it exhausts itself and ceases spontaneously.*—(See *Med. and Chir. Trans. vol. 4, p. 2—5.*) In the third edition of the *First Lines of the Practice of Surgery*, it was sufficiently proved, from several conclusions drawn from the writings of Mr. Pearson (*Obs. on the Effects of various Articles in the Cure of Lues Venerea*), that venereal sores might be benefited, and even healed, under the use of several inert insignificant medicines. And, as I have previously explained the possibility of curing chancres and other venereal complaints without mercury, was long since remarked by Dr. Clutterbuck, who thence very justly inferred, that the healing of a sore without this remedy, was no test that it was not venereal.—(See *Remarks on the Opinions of the late John Hunter*, 1799.)

But although the whole history of the venereal disease, and of the various articles of the materia medica, if carefully reflected upon, must have led to the same conclusion, the truth was never placed in such a view as to command the general belief of all the most experienced surgeons in this and other countries of Europe. I do not mean to say that the truth was not seen and remarked by several of the older writers; for, that it was so, any man may convince himself by referring to several works quoted in the course of this article. But it is to be understood, all indecision could never be renounced as long as prejudices interfered with the only rational plan which could be adopted, with a view of bringing the question to a final settlement; I mean experiments on a large and impartial scale, open to the observation of numerous judges, yet under such control, as ensured the rigorous trial of the practice. Nor could such investigation be so well made by any class of practitioners as the army surgeons, whose patients are numerous, obliged to follow strictly the treatment prescribed, without any power of going from hospital to hospital, or from one surgeon to another, as caprice may dictate, or of eluding the observation of the medical attendants after a seeming recovery. And here I must take the opportunity of stating, that as far as my judgment extends, the most important and cautious document yet extant, on the two questions of the *possibility* and *expediency* of curing the venereal disease without mercury, is the paper of Mr. Rose. For let it not be presumed, that because the army surgeons find the venereal disease curable without mercury, they mean to recommend the total abandonment of that remedy for the distemper, any more than they would argue that *possibility* and *expediency* are synonymous terms. At the time when Mr. Rose published his observations, he had tried the non-mercurial treatment in the Coldstream regiment of guards, during a year and three-quarters, and had thus succeeded *in curing all the ulcers on the parts of generation, which he met with in that period, together with the constitutional symptoms to which they gave rise.* "I may not be warranted in asserting (says this gentleman), that many of these were venereal; but undoubtedly a considerable number of them had all the appearances of primary sores, produced by the venereal virus, and arose under circumstances where there had been at least a possibility of that virus having been applied. *Admitting that there is nothing so characteristic in a chancre as to furnish incontrovertible proof of its nature*, it will yet be allowed, that there are many symptoms common to such sores, although not entirely peculiar to them, and whenever these are met with, there are strong grounds to suspect that they are the effects of the syphilitic virus. In a sore, for instance, appearing shortly after suspicious connexion, where there is loss of substance, a want of disposition to granulate and an indurated margin and base, there is certainly a probability of that poison being present. Among a number of cases of such a description, taken indiscriminately, the probability of some being venereal is materially increased, and must at last approach nearly to a certainty. On this principle, some of the sores here referred to must have been venereal. They were also seen by different surgeons, on whose judgment I would rely, who agreed in considering many of them as well-marked cases of true chancre."—(*Rose, in Med. Chir. Trans. vol. 8, p. 357, &c.*) The men thus treated were examined almost every week for a considerable time after their apparent cure, "both that the first approach of constitutional symptoms might be observed, and that any deception from an underhand use of mercury might be guarded against."—(*P. 359.*) Sixty cases of ulcers on the penis were also cured by Mr. Dease in the York Hospital, by means of simple dressings, the only general remedy being occasional purgatives. The practice was likewise extensively tried by Mr. Whymper and Mr. Good, surgeons of the Guards, with the same kind of success. In Mr. Rose's practice, all idea of specific remedies was entirely laid aside. The patients were usually confined to their beds, and such local applications were employed as the appearances of the sores seemed to indicate. Aperient medicines, antimony, bark, vitriolic acid, and occasionally sarsaparilla were administered.—(*P. 363.*) "*Upon an average* (says Mr. Rose), *one out of every three of the sores thus treated, was followed by some form or other of constitutional affection:* this was in most instances mild and sometimes so slight that it would have escaped notice, if it had not been carefully sought for. The constitutional symptoms were evidently not such as could be regarded as venereal, if we give credit to the commonly received ideas on the subject. *Caries of the bones*, and some of the least equivocal symptoms, *did not occur.* In no instance was there that uniform progress, with unrelenting fury, from one order of symptoms and parts affected to another, which is considered as an essential characteristic of true syphilis."—(*Med. Chir. Trans. vol. 8, p. 422.*) The constitutional symptoms also yielded, without the aid of mercury; and frequently primary sores, corresponding to what had been called the true chancre, with indurated base, were cured in this manner, yet were followed by no secondary symptoms. We are also informed, that "several cases occurred of a cluster of ill-conditioned sores over the whole inner surface of the prepuce: and behind the corona glandis; and also of a circle of small irritable sores, situated on the thickened and contracted ring at the extreme margin of the prepuce. These occasionally produced buboes.' *None of the sores of this description, met with by Mr. Rose, were followed by any constitutional affection.*—(*Vol. cit. p. 370.*) He bears testimony to the ill effects of mercury and stimulants in cases of phagedenic ulcers, and confirms a not uncommon opinion, that they are sel-

dom followed by secondary symptoms, which opinion should be qualified with the condition mentioned by Mr. Guthrie (*Med. Chir. Trans. vol.* 8, *p.* 565), that no mercury be given. Lastly, as I have already stated, Mr. Rose observed, that most of the cases of papular eruptions followed ulcers, which were not very deep, and healed without much difficulty.—(*P.* 399.)

Although the fact of the *possibility* of curing every kind of ulcer on the genitals without mercury has been fully confirmed by the statements of Mr. Guthrie (*Med. Chir. Trans. vol.* 8, *p.* 558 and 576), Dr. J. Thomson (*Edin. Med. and Surg. Journ. for January*, 1818), Dr. Hennen (*Op. cit Nos.* 54 *and* 55, and *Principles of Military Surgery, ed.* 2), Mr. Bacot (*On Syphilis, p.* 26, *&c.*), and many other careful observers; and, although it is of great importance in relation to the removal of an erroneous doctrine concerning the diagnosis; yet the *expediency* of the practice must evidently be determined by other considerations, the principal of which are the comparative quickness of the cures effected with and without mercury; the comparative severity and frequency of secondary symptoms; and the generally acknowledged fact, that a syphilitic primary sore is not indicated with any degree of certainty by its mere external character, or indeed any other criterion hitherto discovered.

Respecting the comparative quickness of the cures of chancres, or reputed chancres, without the aid of mercury, much disagreement prevails in the different reports, even those collected by the same individuals, whose statements must therefore be deemed perfectly impartial, though inconclusive.—(See *Hennen's Military Surgery, ed.* 2, *p.* 536, *&c.*) Some of Mr. Rose's best marked cases of chancre, that is to say, such as were distinguished by the indurated base and circumference, healed in a very short time. But even respecting these, or any other kinds of chancre, no regularity on this point can be found. Mr. Guthrie observes, if the "ulcers were not without any marked appearance, and did not amend in the first fortnight or three weeks, they generally remained for five or seven weeks longer; and the only difference in this respect between them and the raised ulcer of the prepuce was, that this often remained for a longer period, and that ulcers, possessing the true character of chancre, required in general a still longer period for their cure, that is, from six, eight, to ten, and in one case, even twenty-six weeks, healing up and ulcerating again on a hardened base. Those that required the greatest length of time had nothing particular in their appearance that would lead us to distinguish them from others of the same kind which were healed in a shorter time."—(*Med. Chir. Trans. vol.* 8, *p.* 558.) The same writer afterward expresses his belief, that almost all the protracted cases would have been cured in one-half or even one-third of the time, if a moderate course of mercury had been resorted to.

In relation to the question before us, one of the most important documents which I have met with, is an official circular, signed by Sir James M'Grigor and Sir Wm. Franklin, from which it appears that in 1940 cases of primary venereal ulcerations on the penis, *cured without mercury*, between December, 1816, and December, 1818 (including not only the more simple sores, but also a regular proportion of those with the most marked characters of syphilitic chancre), the average period taken up by the treatment when bubo did not exist, was 21 days; with bubo, 45 days.—(See *Hennen's Military Surgery, ed.* 2, *p.* 545.) And it farther appears, that during the period above specified, 2827 chancres, a more considerable proportion of which were probably Hunterian chancres, were treated with mercury, and that the average period required for the cure when there was no bubo, was 33 days; with bubo, 50. As far, therefore, as a judgment can be formed from this official estimate, and no calculation is ever likely to be furnished on a larger or more impartial scale, the evidence tends to prove, that primary sores may generally be cured rather sooner without than with the administration of mercury. But as practitioners are not obliged to restrict themselves either to the mercurial or non-mercurial practice, I am of opinion that the total rejection of mercury is by no means justified by any facts yet before the public, concerning the time requisite for the cure on either plan; because, as it is universally admitted that *some* cases are very tedious unless mercury be given, neither reason nor experience will sanction the exclusive adoption of only one mode of practice, whether the backwardness to heal exist or not. On the contrary, as far as the consideration of time has weight, prudence and common sense teach us to diversify the treatment according to circumstances. But it may be inquired, since the backward disposition of a sore to heal cannot be known at first by its mere appearance, should the treatment begin with mercury or not? Now, although late writers dwell very much on the impossibility of judging of the nature of a sore by its look alone, one fact is certain, that some ulcers on the penis have a clean appearance from their very commencement; some cases are simple excoriations; and others, though ill-conditioned, are so small, that a fair chance offers itself of destroying every part of the disease with caustic. In all such cases, I should never commence with mercury. With respect to phagedenic and sloughing chancres, repeated experience has convinced me, that they are cases in the first stage of which, at all events, mercury should always be avoided; and I believe, with Mr. Guthrie, that when this is strictly done, secondary symptoms are rare. One sore of this kind was long ago pointed out by Mr. Pearson, as not requiring mercury, and the attention of surgeons has been of late particularly directed to it by Mr. Bacot. "It is characterized by a great derangement of the general health, by a high state of inflammation of the part, by great local pain, and proceeds rapidly to the destruction of the parts. The situation of this sore is most commonly in the angle between the prepuce and glans penis; and those of a full habit of body, the young and the vigorous, are most liable to its attack. The most prompt and vigorous antiphlogistic means are necessary to arrest the progress of this sore; and the blood taken away in these cases presents the usual inflammatory appearances, frequently in a very high degree. The exhibition of mercury in this species of sore is highly mischievous, and productive of the worst consequences; nor does it often happen that secondary symptoms succeed, &c.—(*On Syphilis, p.* 57.) Here, according to Mr. Pearson's observations, made many years ago, mercury is not perhaps necessary for the security of the constitution; but I conceive it might be more correct to say that the safety of the constitution actually requires that mercury should be strictly avoided, because there is some ground for believing that, in these instances, it is not only injurious to the local disease, but conducive to secondary symptoms. However, if the latter symptoms should arise, notwithstanding mercury has not been administered during the cure of the ulcer, alterative doses of that medicine may still be useful, as Mr. Carmichael observes, when the disease is in the wane, but not until then, previously to which period, the best internal remedies are antimonials, sarsaparilla, guaiacum, compound powder of ipecacuanha, arseniate of kali, the nitrous acid, and nitro-muriatic bath.—(See *Obs. on the Symptoms, &c. of the Venereal Disease, p.* 209.)

With respect to chancres with a hardened base and margin, it certainly appears that many of them have healed tolerably fast without mercury; but a large proportion of them were tedious when that medicine was not employed.—(See three cases recorded in the work last quoted.) It may be thought, however, that the official document circulated by Sir James M'Grigor and Sir William Franklin, tends to prove that, at all events, these sores heal sooner without than with mercury. But this conclusion seems hardly allowable, because, as these faithful and impartial reporters have sensibly remarked, the 2827 sores treated with mercury may be fairly presumed to have partaken of the character of Hunter's chancre in a greater proportion than the 1940 primary sores treated without mercury.—(See *Hennen's Military Surgery, p.* 545.) Consequently, though the sores treated with mercury seem, on the average, to have healed more slowly than others treated without it, yet it is to be taken into the account, that a larger number of the first cases were ulcers with a hardened base and margin, and that if they had not had the mercurial treatment extended to them, it is possible their complete cure might generally have been still more tedious. As the evidence now stands, therefore, I conceive it right to employ mercury with moderation, for all sores on the penis having the characters of the Hunterian chancre, and appearing after a suspicious connexion.

A consideration, however, which ought to have greater influence than the slowness or quickness of the cure of primary sores with and without mercury, is the question, whether, upon the average, secondary symptoms are more frequent after the non-mercurial practice than the other? On this most interesting point the reports vary, as indeed they do on almost every matter in the investigation, excepting the facts of the possibility of curing all forms of the venereal disease without mercury, the great rarity of any affection of the bones, and the general mildness of the secondary symptoms, when that medicine is not employed. On all these points the testimonies are strong and convincing. But while Mr. Rose found secondary symptoms take place in one-third of his cases treated without mercury (*Med. Chir. Trans. vol.* 8, *p.* 422), the proportion in the York and some other hospitals, was only about one-tenth.—(*Vol. cit. p.* 559.) In the 1940 cases of primary sores on the penis, treated without mercury in the army hospitals, between December, 1816, and December, 1818, there were only 96 instances of secondary symptoms of different sorts, or not more than one-twentieth. But the proportion of cases of secondary symptoms in the cases of primary ulcers treated with mercury was still smaller, and this in an important degree, being only 51 out of 2827 cases, or about one-fifty-fifth. Were it not necessary to make a considerable allowance for the probable circumstance of the Hunterian chancre prevailing most in the cases treated with mercury, a point admitted by Sir James M'Grigor and Dr. Franklin, we should here have a powerful and decisive evidence in favour of the general superiority of mercury for the prevention of secondary symptoms. Nor am I certain that the conclusion can be much weakened by the probability of the difference here alluded to, because from the evidence of late brought to light respecting the nature of the class of diseases which go under the name of syphilis, we have no right to infer that what has been called the true or Hunterian chancre is more disposed than some other primary sores to occasion secondary symptoms. Indeed, Mr. Guthrie declares, in the cases referred to in his paper, that when mercury was not used, these symptoms more frequently followed the raised ulcer of the prepuce, than the true characteristic chancre of syphilis affecting the glans penis.—(*Méd. Chir. Trans. vol.* 8, *p.* 577.) On the whole, as the reports now stand, and as far as I can judge from cases which I have seen myself, the secondary symptoms are more frequent when primary ulcers are promiscuously treated without mercury. But it by no means follows from this fact, that the way to have the smallest possible number of cases of secondary symptoms is to employ mercury in all instances of sores on the genitals. This both reason and experience contradict, inasmuch as mercury given in cases which do not require it for the security of the constitution, is frequently itself a source of cutaneous diseases, sore throats, and nodes, which, without its baneful influence, would never have occurred. The prudent course seems here to be to exercise our judgment and discretion, and to be guided, in some measure, by the appearance and progress of the sore, according to principles already suggested; for though the look of a sore may not, in the present state of our knowledge, always enable us to form a certain inference respecting the risk of secondary symptoms if mercury be omitted, it cannot be said that the danger would be positively obviated by having recourse at once to mercury in every kind of primary sore; and notwithstanding every thing which has been lately published, I still flatter myself, that surgeons, accustomed to see much of venereal cases, can yet distinguish excoriations, herpes of the prepuce, biles, simple healthy sores, and some other common ailments (see *Evans on Ulcerations of the Genital Organs*, 8*vo. Lond.* 1819), from ulcers, by which the constitution is liable to be affected. Until farther data exist, I cannot venture to lay down other directions about the treatment of primary sores. It is with pleasure, however, that I subjoin the advice of other gentlemen, whose sentiments and talents deserve respect, though their opinions may not exactly agree with my own. "In every primary ulcer (says Dr. Hennen), I would give up the idea of using mercury at first, treating it as if it were a simple ulceration, by cleanliness, rest, and abstinence, and applying to it the most simple and mildest dressings. If the sore did not put on a healing appearance in a reasonable time, the extent of which must depend upon the circumstances of the patient, I should make use of more active dressings. But if, beyond all calculation, it remained open, I should certainly not sacrifice every consideration to a dislike of mercury, knowing how many persons have been seriously benefited by a judicious and mild administration of that remedy."—(*On Military Surgery, edit.* 2, *p.* 518.) When primary ulcers resist common means a certain time, Mr. Bacot would also have recourse to mercury.—(*On Syphilis, p.* 69.) Like me, however, the latter author does not approve of invariably postponing that remedy until the latter criterion, viz. the backwardness of the sore to be healed by other methods, is afforded.

Whenever the employment of mercury in this work is recommended, I am very far from wishing to be thought an advocate for *pushing* that medicine, as the phrase is. On the contrary, experience has fully convinced me, that in no forms of chancre, nor in any other stages of the venereal disease, is it proper to exhibit mercury in the unmerciful quantity, and for the prodigious length of time, which custom, ignorance, and prejudice used to sanction in former days. Violent salivations, at all events, ought to be for ever exploded.

When I was an articled student at St. Bartholomew's Hospital, most of the venereal patients in that establishment were seen with their ulcerated tongues hanging out of their mouths; their faces prodigiously swelled; and their saliva flowing out in streams. The wards were not sufficiently ventilated, and the stench was so great that the places well deserved the appellation of *foul*. Yet, notwithstanding mercury was thus *pushed* (as the favourite expression was), it was then common to see many patients suffer the most dreadful mutilations, in consequence of sloughing ulcers of the penis; many unfortunate individuals, whose noses and palates were lost; and others who were afflicted with nodes and dreadful phagedenic sores.

Happily, at the present day, this attachment to violent salivations no longer prevails; simple excoriations and common ulcers are more attentively discriminated; and, even in what are reputed to be true syphilitic chancres, mercury is seldom given, except in very moderate doses, or such quantities as only gently affect the gums and salivary glands. The surgeon, now no longer blinded with the continual fear of the rapid and furious progress of syphilis when not duly resisted by mercury, avoids the very mode of practice which was itself the cause of all the aggravated forms of the disease. The consequence is, that very bad instances of the ravages of lues venerea are now hardly ever observed, except from the neglect and intemperance of patients themselves; and the few aggravated cases which are met with, even in hospitals, are generally in that state previously to their admission. Another benefit also resulting from modern investigations, which prove that chancres, and all other varieties of the venereal disease, do not *absolutely* require mercury for their cure, is the safety with which it is now known that the use of such medicine may be postponed, where the patient's present state of health would not well bear its exhibition. And I know that an ignorance of this fact formerly caused the death of many poor sufferers.

The greater present mildness of syphilitic diseases in England, I ascribe chiefly to the more judicious treatment now adopted, and not to any change or modification in the nature of the disorder. There are others, however, who may think as Mr. Fergusson does with regard to syphilis in Portugal, that the disease has exhausted a great deal of its virulence from long continuance among us. But before we are altogether justified in drawing such a conclusion, we must forget all the bad practice which prevailed in former days, and which, in my opinion, is sufficient to account for the more severe forms in which syphilis then presented itself; though not for the ravages of that acute quickly spreading, and fatal disorder which broke out in the French army at Naples, at the close of the 15th century. According to my own judgment, this was decidedly a very different disease from any venereal maladies with which we are now acquainted; too different indeed to be accounted for either by any spontaneous alteration of its own, or by any improvements in practice.

According to Mr. Hunter's ideas, the most simple method of treating a chancre is to extirpate it with

caustic or the knife, whereby it is reduced to the state of a common sore or wound, and heals up as such. However, he sanctions this practice only on the first appearance of the chancre, when the surrounding parts are not yet contaminated; for he says it is absolutely necessary to remove the whole of the diseased part, and this object is exceedingly difficult of accomplishment when the disease has spread considerably. When the chancre is situated on the glans penis, he thought touching the sore with the lunar caustic preferable to cutting it away, because the hemorrhage from the cells of the glands would be considerable after the use of the knife.

The caustic should be pointed at the end, like a pencil, in order that it may only touch such parts as are really diseased; and its application should be repeated till the surface of the sore, after the separation of the last sloughs, assumes a red and healthy appearance, when it will heal like any other sore made with caustic.

When the sore is on the prepuce, or the common skin of the penis, and in an incipient state, the same practice may be adopted with success. When the chancre is large, however, it cannot be destroyed with the argentum nitratum, which does not extirpate the increasing sore deeply enough. In such cases, Mr. Hunter thought that the potassa cum calce might answer better. When the caustic could not be conveniently employed, this author sometimes recommended the excision of chancres, a plan which he had adopted himself, and the part afterward healed with common dressings. However, says he, as our knowledge of the extent of the disease is not always certain, and as this uncertainty increases with the size of the chancre, the cure must be in some measure promoted by proper dressings, and it will be prudent to dress the sore with mercurial ointment. When a chancre is destroyed almost immediately on its first appearance, Mr. Hunter believes that there is little danger of the constitution being infected, as it is reasonable to conclude that there has not been time for absorption to take place. However, on account of the impossibility of being certain on this point, he recommends mercury to be given from motives of prudence, the quantity of which medicine, he says, should be proportioned to the duration and progress of the sore. When the chancre is large, Mr. Hunter deems mercury *absolutely necessary*; and he conceives that very little good is to be done by the extirpation.

Among modern advocates for the application of caustic to chancres, Delpech is one of the most zealous, and the nitrate of mercury is that which he commonly employs; he abstains from the practice, however, when much inflammation is present.—(*Chir. Clinique, t.* 1.)

With respect to dressings for chancres, Mr. Hunter seems to have placed a good deal of confidence in those which contain mercury; but I do not believe that the same attachment to them prevails now which existed twenty years ago. And the established fact of mercury not being *absolutely* necessary in any way for the cure of different venereal sores, must have the effect of removing some prejudices on this part of the subject. As common mercurial ointment is always more or less rancid, I have found it in many cases a bad kind of dressing, and now seldom apply it to ulcerated surfaces. In ordinary cases, I believe astringent lotions, made with the sulphate of copper, acetate of lead, alum, &c. answer the best. Some chancres are indolent and require stimulants, like the hydrargyri nitrico-oxydum blended with ointment, the unguentum hydrargyi nitrati more or less weakened, or a solution of the nitrate of silver. Mr. Hunter, always partial, even in cases of indolent chancres, to mercurial dressings, expresses his preference to a salve containing calomel, as being more active than common mercurial ointment. In phagedenic and sloughing chancres, the carrot and fermenting poultices, solutions of the extracts of hemlock and opium; but particularly bread and water poultices with opium, and lotions of the arseniate of potassa, containing arsenic, or nitrous acid, and nitrate of silver, merit trial.

In general, Mr. Hunter was an advocate for changing the dressings very often, because the matter separates them from the sore, so as to diminish their effect. He states, that changing the applications thrice a day will not be found too often, particularly when they are in the form of an ointment.

When the venereal nature of a chancre is removed, the sore frequently becomes stationary; in which case, Mr. Hunter observes, that new dispositions have been acquired, and the quantity of disease in the part has been increased. When chancres are only stationary Mr. Hunter says, they may often be cured by touching them slightly with the lunar caustic.

In these cases, no cicatrization seems possible till the contaminated surface, or the new flesh which grows on that surface, has either been destroyed or altered When sores are situated under the prepuce, where they are concealed by a phymosis, some emollient or gently astringent lotion should frequently be injected under the foreskin, so as to wash out any matter which might otherwise lodge there and cause additional irritation.

Contrary to the doctrines which the facts of modern experience have now fully established, Mr. Hunter believed that *mercury should be given in every case of chancre*, however slight, and even when it has been destroyed by caustic, or other means, on its very first appearance. *The remedy*, he says, *should be continued for some time after the chancre has healed, in order to hinder the venereal disposition from forming.* Here we find even Hunter himself falling into some inconsistencies; for, in other parts of his work, he seems to approve of the principle of giving mercury only when actual and visible disease exists, because it cannot cure the disposition to it even if it exists. Now, as the chancre is cured, no farther absorption of the virus from it is possible; and whatever *disposition* to the disease can arise from absorption must have already been formed, and therefore cannot be prevented; and though, according to Mr. Hunter's own theory, the virus has been long ago expelled from the system together with some of the excretions, mercury is recommended with the view of protecting the constitution.

However, if Mr. Hunter's explanations are not altogether satisfactory on this part of the subject, I believe the fault is in his theory; because, in cases where mercury is deemed advisable, general experience appears to sanction the practice of continuing its use for some time after the chancre is perfectly healed. Yet many exceptions to this rule present themselves; for, if a chancre is large and very long in healing, its syphilitic character is generally extinct a good while before cicatrization is completed, and perseverance in mercury, under these circumstances, would be both an absurd and a dangerous practice.

Hence, in a great measure, the cause of the numerous instances of the *mercurial* disease, as Mr. Mathias has named it, and which in former days did far more mischief than syphilis itself.—(See *An Inquiry into the History and Nature of the Disease produced in the Human Constitution by the Use of Mercury*, 3*d ed.* 8*vo. Lond.* 1816.) This part of the subject is noticed by Mr. Hunter, who states that, in very large chancres, it may not always be necessary to continue either the external or internal administration of mercury till the sore is healed; for the venereal action is just as soon destroyed in a large chancre as it is in a small one, since every part of the sore is equally affected by the medicine, and of course cured with equal expedition. But in regard to cicatrization, circumstances are different, because a large sore is longer than a small one in becoming covered with skin. Hence, according to Mr. Hunter, a large chancre may be deprived of its venereal action long before it has healed; while, on the other hand, a small one may heal before the syphilitic affection has been destroyed. In the latter case, he represents it as most prudent, both on account of the chancre and constitution, *to continue the employment of mercury a little while after the sore is healed*; advice which, as I have already stated, is at variance with certain parts of his own theory, however well justified it may be by experience.

As Mr. Hunter has explained, chancres, both in men and women, often acquire during the treatment new dispositions, which are of various kinds, some retarding the cure and leaving the parts in an indolent thickened state after the cure is accomplished. In other instances, a new disposition arises, which utterly prevents the parts from healing, and often produces a much worse disease than that from which it originated. Such new dispositions may lead to the growth of tumours. They are more frequent in men than women, and generally occur only when the inflammation has been violent from some peculiarity of the parts or

constitution. They have sometimes been considered as cancerous.

Among the diseases in question, Mr. Hunter notices those continued and often increased inflammations, suppurations, and ulcerations, which become diffused through the whole prepuce, and also along the common skin of the penis, which becomes of a purple hue, attended with such a general thickening of the cellular membrane as makes the whole organ appear considerably enlarged. The same writer observes, that the ulceration on the inside of the prepuce will sometimes increase, and run between the skin and the body of the penis, and eat holes through different places till the whole is reduced to a number of ragged sores. The glans often shares the same fate, till more or less of it is gone. Frequently, the urethra in this situation is wholly destroyed by ulceration, and the urine is discharged some way farther back. The ulceration, if unchecked, at length destroys all the parts. In this acute case, prompt relief is demanded: but often the proper mode of treatment cannot be at once determined, owing to our ignorance with respect to the exact nature of the peculiar cause of the disease. Mr. Hunter states, that the decoction of sarsaparilla is often of service when given in large quantities, and that the extract of hemlock and sea-bathing are sometimes capable of effecting a cure. According to my own experience, the omission of mercury is here the most essential point.

Sometimes, after a chancre has healed, the cicatrix breaks out again, and puts on the appearances of the preceding sore. Occasionally similar diseases break out in different places from that of the cicatrix. Mr. Hunter believes that they differ from a chancre in generally not spreading so fast, nor so far; in not being so painful, nor so much inflamed; in not having such hard bases as venereal sores have; and in not producing buboes. This writer is of opinion that they are not venereal, and he states that they are very apt to recur.

Mr. Hunter does not specify any particular mode of cure for all these cases; but he mentions one instance which seemed to be cured by giving forty drops of the liquor potassæ, every evening and morning, in a basin of broth; and he adverts to another case, which was permanently cured by sea-bathing.

In some instances, after a chancre has healed, the parts, as Mr. Hunter remarks, do not ulcerate, but appear to become thickened and indurated. Both the glans and prepuce seem to swell, so as to form on the end of the penis a tumour or excrescence shaped very much like a cauliflower, and, when cut into, showing radii running from its base or origin towards the external surface. It is extremely indolent, and not always a consequence of the venereal disease; for Mr. Hunter has seen it arise spontaneously.

No medicine seems to be at all likely to cure the disease; the only successful means is to amputate a considerable part of the penis, and then to keep a proper catheter introduced in the urethra.

Another disposition, induced by the previous occurrence of chancres, is that to excrescences, or cutaneous tumours, called warts. These are frequently considered, not simply as a consequence of the venereal poison, but as possessed of its specific disposition; and therefore, says Mr. Hunter, surgeons have recourse to mercury for the cure of them; and it is said that such treatment often removes them. This eminent practitioner never saw mercury produce this effect, although the medicine was given in sufficient quantity to cure recent chancres and a lues venerea in the same person.—(See *Wart.*)

Mr. Hunter takes notice of sloughs which occur in the tonsils from the effect of mercury on the throat, and are apt to be mistaken for venereal complaints. He also mentions, that sometimes when the original chancre has been doing well and been nearly healed, he has seen new sores break out on the prepuce near the first, and assume all the appearance of chancres.

When, in the treatment of chancres, a bubo arises, while the constitution is under the influence of a sufficient quantity of mercury to cure such sores, which medicine has also been rubbed into the lower extremity on the same side as the bubo, Mr. Hunter suspects that the swelling in the groin is not venereal, but is produced by the mercury. In these cases, he always preferred conveying mercury into the system in some other manner.

With respect to the treatment of chancres in women, since it is difficult to keep dressings on the parts, Mr Hunter advises the sores to be frequently washed with some mercurial solution, and speaks of one made with oxymuriate of mercury as being perhaps the best, since it will act as a specific and stimulant also when this is requisite. When the chancres, however, are irritable, they are to be treated in the same manner as similar complaints in men. When the sores extend into the vagina, this passage must be kept from becoming constricted or closed, by the introduction of lint.

Sometimes, after a chancre and all venereal disease are cured, the prepuce continues thickened and elongated, so that the glans cannot be uncovered; perhaps the case is often without remedy. Mr. Hunter, however, very properly recommends trying every possible means; and he informs us, that the steam of warm water, hemlock fomentations, and cinnabar fumigations are frequently of singular service.

When the thickening and enlargement of the prepuce cannot be removed by applications, all the portion anterior to the glans penis may be cut away.—(See *Phymosis.*)

Bubo.—The immediate consequence of a chancre, which is called a bubo, and also the remote effects implied by the *constitutional or secondary symptoms*, arise from the absorption of recent venereal matter from some surface where it has either been applied or formed.

We are already aware that Mr. Hunter believed the matter of gonorrhœa to be capable of communicating the venereal disease. Hence, he explains in the following terms, the three ways in which he thought a bubo might arise in consequence of absorption. He observes, that the first and most simple manner is when the matter, either of a gonorrhœa or chancre, has only been applied to some sound surface, without having produced any local effect on the part; but has been absorbed immediately after its application. Mr. Hunter affirms, that he has seen instances of this kind, though he confesses that they are very rare, and that in most cases, apparently of this nature, a small chancre may be found to have existed.

The second mode of absorption, or that taking place in a gonorrhœa, Mr. Hunter represents as more frequent. That secondary symptoms do occasionally follow gonorrhœa is now commonly admitted, though whether they differ essentially from those which follow true chancres, is a point not yet completely settled. Delpech describes them as of the same nature (*Chir. Clinique, t.* 1); but his facility of belief in the multiplied effects of syphilis and gonorrhœa is almost unbounded. On a point of this kind, therefore, I should not attach much importance to his opinion. However, as far as Mr. Carmichael's experience goes, there is a difference, a part of which consists in the eruption being of the papular kind, as it is also after many instances of simple primary ulcers.—(See *Obs. on the Symptoms, &c. of Venereal Diseases*, 8*vo. Lond.* 1818.)

The third mode is the absorption of matter from an ulcer, which may either be a chancre or a bubo. This mode is by far the most common, and it proves, with many other circumstances, that a sore or ulcer is the most favourable for absorption. Mr. Hunter believed, that absorption was more apt to take place from sores on the prepuce, than those on the glans.

A fourth mode of absorption is from a wound; a case which, according to Delpech, is almost constantly followed by an eruption on the face, soon extending all over the body, and very quickly followed by sore throat, periostoses, and pains in the bones. In short, his idea is, that when the poison is absorbed from a wound, especially one that has not suppurated, its operation is peculiarly rapid and violent.—(*Chir. Clinique, t.* 1, *p.* 334.)

Mr. Hunter notices, that what is now commonly understood by a bubo is a swelling taking place in the absorbing system, especially in the glands, and arising from the absorption of some poison, or other irritating matter. When such swellings take place in the groin, they are called buboes, whether they proceed from absorption or not.

Mr. Hunter regards every abscess in the absorbing system as a bubo, whether in the vessels or the glands, when it originates from the absorption of venereal matter.

The matter is taken up by the absorbent vessels, and is conveyed by them into the circulation. In its passage through these vessels it often affects them with

the specific inflammation. The consequence is the formation of buboes, which are venereal inflammations or abscesses of the lymphatic glands or vessels. The sores resulting from their being opened, or spontaneously bursting, are exactly similar to a chancre in their nature and effects, the only difference being in regard to size. As the lymphatic vessels and glands are irritated by the specific matter before it has undergone any change in its passage, the inflammation produced and the matter secreted partake of the specific quality.

Inflammation of the absorbent vessels themselves is not nearly so frequent as that of the glands. In men such inflammations, in consequence of chancres upon the glans or prepuce, generally appear like a cord, leading along the back of the penis from the sores. Sometimes the absorbents inflame in consequence of the thickening and excoriation of the prepuce in gonorrhœa. The indurated lymphatics often terminate insensibly near the root of the penis, or near the pubes; while, in other instances, they extend farther to a lymphatic gland in the groin. Mr. Hunter believed, that this affection of the absorbent vessels is truly venereal. The formation of a hard cord, he conceived, arose from a thickening of the coats of the absorbents, and from an extravasation of coagulable lymph on their inner surface.

A cord of the above kind often suppurates, sometimes in more places than one, so as to form one, two, or three buboes, or small abscesses, in the body of the penis.

Inflammation much more frequently affects the absorbent glands than the vessels. The structure of the former parts appears to consist of the ramifications and reunion of the absorbent vessels. From this structure, observes Mr. Hunter, we may reasonably suppose, that the fluid absorbed is in some measure detained in the glands, and thus has a greater opportunity of communicating the disease to them than to the distinct vessels.

Swellings of the absorbent glands may originate from other diseases, and should be carefully discriminated from those which arise from the venereal poison. With this view, Mr. Hunter advises us first to inquire into the cause, in order to ascertain whether there is any venereal complaint at some greater distance from the heart, such as chancres on the penis, or any preceding disease in this situation. He recommends us to inquire whether any mercurial ointment has been at all applied to the leg and thigh on the diseased side; for mercury, applied to those parts for the cure of a chancre, will sometimes cause glandular enlargements, which are occasionally mistaken for venereal buboes. This irritation of the inguinal glands by the mechanical action of mercurial ointment, has also been particularly noticed by Professor Assalini, who states that he has had frequent opportunities of convincing himself of the fact.—(See *Manuale di Chirurgia*, *p.* 67.) Mr. Hunter reminds us to observe whether there has been any preceding disease in the constitution, such as a cold, fever, &c. The quick or slow progress of the swelling is likewise to be marked, and the tumour must be distinguished from femoral hernia, lumbar abscesses, and aneurisms of the crural artery. In particular cases it would appear, that some time elapses before the venereal matter produces its effects on the absorbent glands after its absorption. Mr. Hunter notices, that sometimes, at least, six days transpire first; a circumstance which can only be known by the chancres having healed six days before the bubo began to appear. However, as the last matter of a chancre is probably not venereal, he infers, that in cases of this kind absorption must have taken place earlier than other considerations would lead one to suppose. According to Mr. Hunter, in general, only the glands nearest to the seat of absorption are attacked. Thus, when the matter is taken up from the penis in men, the inguinal glands are affected; and, when from the vulva in women, those glands swell which are situated between the labium and thigh, and the round ligaments.

It was one of Mr. Hunter's opinions, that only one gland at a time is commonly affected by the absorption of venereal matter. If this sentiment be correct, the circumstance may be considered as a kind of criterion between venereal and other buboes. The second *order* of lymphatic vessels and glands are never affected; as, for instance, those along the iliac vessels or back. Mr. Hunter informs us, that he also observed, that when the disease was contracted by a sore or cut upon the finger, the bubo occurred a little above the bend of the arm, by the side of the biceps muscle, and no swelling of this sort formed in the armpit. However, he had heard of a few rare cases in which a swelling in the axilla was also produced.

When buboes arise from a venereal disease on the penis, they are situated in the glands of the groin. When a bubo arises from a gonorrhœa, either groin may be attacked. But when the disease originates from a chancre, the bubo most frequently takes place in the nearest groin.

The situation of the absorbent glands, however, is not always exactly the same, and the course of the lymphatics therefore is subject to some variety. Hence, Mr. Hunter has seen a venereal bubo produced by a chancre on the penis, situated a considerable way down the thigh; he has also often seen buboes as high as the lower part of the belly, before Poupart's ligament; and sometimes near the pubes. At the present day, swellings of the femoral glands are rarely considered to be venereal.

I am now (Nov. 1829) attending a gentleman who had a small sore on the penis, followed by a bubo in each groin; one of them restricted to the femoral glands, the other to the inguinal. The sore was nearly well when he applied to me, and I desired him, for the sake of security, to continue the blue pill and aperient medicines a little while longer. The ulcer healed; but the buboes remained indolent and stationary for nearly a month afterward, notwithstanding frictions with camphorated mercurial ointment, the application of soap and mercurial plasters, and the use of the compound calomel pill, with the decoct. sarsap. c. At length, the bubo in the femoral glands suppurated. I punctured it, and a thin fluid was discharged, together with flakes of a substance like wet paper. The swelling underwent some diminution, yet did not get completely well, and emitted, from time to time, the same kind of discharge which it did at first. The other bubo, however, was partially resolved without suppurating at all; and, at the end of about two months, as the patient had merely two chronic indurations in the groins, he left town for the seaside, in the hope that they would undergo a farther diminution there. In two or three weeks, or more, instead of being cured, he returned to me with an abscess in the groin, which had previously suppurated, and a phagedenic ulceration, as large as a shilling, in the other groin, with its bottom and edges all covered with white pulpy sloughs. He had at the same time a sore throat, and an eruption of about fifteen spots on the face, resembling small biles, with a conical sloughy elevated point on each of them. There was also a circular spot, of large size, on one of the arms, with a dark-coloured slough in its centre. The patient suffered severely from wandering pains in his limbs, head, and even different parts of his trunk, and complained much of loss of rest, and debility. He now tried in succession the nitrous acid, with compound decoction of sarsaparilla, and the sulphate of quinine; the liquor arsenicalis; the conium united with calomel; the sulphuric acid; the oxymuriate of mercury; and various other alterative and tonic remedies; but hitherto the only amendment has been that of the groins. His throat and the ulcer on his arm are much worse, and so is his general health. During the last fortnight he has been at Leamington, where he is attended by Mr. John Pritchard, who has sent me a very unfavourable account of the present state of the case. In this example, the occurrence of a sloughy surface or point in every appearance which presented itself led me to regard the disorder as a specimen of what has been termed the phagedenic venereal disease; and the circumstance of one of the buboes being confined to the femoral glands also inclined me to the belief, that the case was not one of true syphilis. Yet, hitherto no alterative plans of treatment have answered; and it remains to be seen whether the freer use of mercury, mercurial fumigations of the throat, tonics, and a generous diet, and confinement to the house, to which the patient has not yet submitted, will bring about a cure.

The seat of absorption is more extensive in the female sex, and the course of some of the absorbents is also different. Hence, buboes in women may occur in three situations, two of which are totally different from those in men.

When chancres are situated forwards near the meatus urinarius, nymphæ, clitoris, labia, or mons veneris, the absorbed matter is generally conveyed along one of

both of the round ligaments; and the buboes are formed in those ligaments, just before they enter the abdomen. Mr. Hunter suspected such buboes not to be glandular ones, but only inflamed absorbents.

When chancres are situated far back, near or on the perinæum, the absorbed matter is carried forwards along the angle between the labium and the thigh, to the glands in the groin, and often, in this course, small buboes are formed in the absorbents, similar to those *abscesses* which occur on the penis in men.

When the effects of the poison do not rest here, a bubo in the groin may be occasioned in the same manner as in men.

Owing to the difficulty of being sure that women are quite free from infection, it is often more difficult to decide in them than in men whether a bubo is venereal or not. In men who have had no local complaint, the bubo can only be venereal when direct absorption from the surface of the skin has taken place.

A bubo, says Mr. Hunter, commonly begins with a sense of pain, which leads the patient to examine the part, where a small hard tumour is to be felt. This increases like every other inflammation that has a tendency to suppuration, and unless checked, pus forms, and ulceration follows, the matter making its way to the skin very fast.

The above celebrated writer remarks, however, that some cases are slow in their progress. This circumstance he imputes either to the inflammatory process being kept back by mercury or other means, or to its being retarded by a scrofulous tendency.

The inflammation, he says, is at first confined to the gland, which may be moved about in the cellular membrane; but when the part has enlarged, or when the inflammation and suppuration are more advanced, the surrounding parts become more inflamed, and the tumour is more diffused. Some buboes become complicated with an erysipelatous and œdematous affection, by which they are rendered more diffused and less disposed to suppurate.

Mr. Hunter allows, that to distinguish with certainty the true venereal bubo from other swellings of the glands in the groin may be very difficult. He represents the true venereal bubo, in consequence of a chancre, as being most commonly confined to one gland. It preserves its specific distance till suppuration has taken place, and then becomes more diffused. It is rapid in its progress from inflammation to suppuration and ulceration. The suppuration is commonly large, considering the size of the gland, and there is only one abscess. The pain is very acute, and the inflamed part of the skin is of a florid red colour.

Mr. Hunter describes such buboes as arise without any visible cause, as being of two kinds. One sort inflame and suppurate briskly. These he always suspected to be venereal, although he allows there was no proof of it, and only a presumption deduced from the quick progress of the disease.

The second kind are generally preceded and attended with slight fever or the common symptoms of a cold, and they are, for the most part, indolent and slow in their progress. If they are quicker than ordinary, they become more diffused than venereal buboes, and they are often not confined to one gland. When very slow, they give but little sensation; but, when quicker, the sensation is more acute, though not so much so as in venereal cases. They usually do not suppurate, and often become stationary. When they do suppurate, it is in a slow manner, and frequently in more glands than one, while the inflammation is more diffused and not considerable, in relation to the swelling. The matter makes its way to the skin slowly, and the part affected is of a more purple colour. Sometimes the abscesses are very large, yet not painful.

In considering whether the swellings of the inguinal glands are or are not venereal, the first thing to be attended to is, whether or not there are any venereal complaints. If there are none, Mr. Hunter observes, that there is a strong presumptive proof that the swellings are not venereal. When the swelling is only in one gland, very slow in its progress, and gives but little or no pain, it is probably merely scrofulous. However, when the swelling is considerable, diffused, and attended with some inflammation and pain, the constitution is most probably affected with slight fever, the symptoms of which are, lassitude, loss of appetite, want of sleep, small quick pulse, and an appearance of approaching hectic. Such swellings are long in getting well, and do not seem to be affected by mercury, even when promptly applied.

Mr. Hunter mentions his having seen the above affection of the groin, together with the constitutional indisposition, take place where there were chancres; and he was puzzled to determine, whether the disease in the groin was sympathetic from derangement of the constitution, or whether it arose from the absorption of matter. He had long suspected that there was a mixed case, and was at last certain that such a case might prevail. He had seen instances, in which the venereal matter, like a cold or fever, only irritated the glands to disease, producing in them scrofula, to which they were disposed.

In such cases, says Mr. Hunter, the swellings commonly arise slowly, give but little pain, and if mercury be given to destroy the venereal disposition, their progress is accelerated. Some suppurate while under this resolving course; and others, which probably had a venereal taint at first, become so indolent, that mercury has no effect upon them, and, in the end, they either get well of themselves or by other means.

According to Mr. Hunter, buboes are local complaints.

When a bubo is judged to be venereal, and only in an inflamed state, an attempt is to be made to resolve the swelling. The propriety of the attempt, however, depends on the progress which the disease has made. If the bubo be very large, and suppuration appears to be near at hand, resolution is not likely to be effected. When suppuration has already taken place, Mr. Hunter much doubted the probability of any success attending the endeavour, which now may only retard the suppuration and protract the cure.

The resolution of these inflammations, says Mr. Hunter, depends *principally on mercury, and almost absolutely on the quantity which can be made to pass through them. When suppuration has taken place, the cure also depends on the same circumstances.* Hence, he recommended the mercury to be applied to such surfaces as allow the remedy, when absorbed, to pass through the diseased gland. In this manner he conceived that the disease in the groin might be subdued, and that the constitution would be less likely to be contaminated. At the same time, he admitted that the situation of many buboes is such, as not to have much surface for absorption beyond them; for instance, the buboes on the body of the penis, arising from chancres on the glans or prepuce. This principle has been much insisted upon by Delpech in his late work.—(*Chir. Clinique, t.* 1, *p.* 301.)

As venereal buboes are, in effect, a consequence of chancres or venereal sores, and glandular swellings in the groin may take place from other kinds of sores or local irritations, and even from various constitutional causes, while modern surgeons profess their incapacity always to pronounce the character either of a primary sore or a bubo by its first appearance and progress, it is evident that the same difficulties present themselves here as in cases of primary sores, respecting the principles by which the treatment should be guided. It is likewise to be remembered, that *buboes*, when supposed to be decidedly syphilitic, *are not*, as Mr. Hunter imagined, *absolutely incurable without mercury.* The firm confidence, also, which Mr. Hunter had, and Delpech still has, in the doctrine of the benefit derived from the practice of rubbing mercury into surfaces from which it would be conveyed directly to the diseased glands, so as both to resolve the swelling and preserve the constitution, is not now regarded as an unquestionable subject. As Mr. Bacot has judiciously remarked, there is some inconsistency in Mr. Hunter's own statements upon this point; for in one place he affirms, that mercury, applied to the legs and thighs for the cure of a chancre, will sometimes cause, instead of dispersing, a bubo.—(*P.* 404.) And Mr. Bacot believes himself, that mercury as frequently promotes the suppuration of buboes as their dispersion.—(*On Syphilis, p.* 74.) And respecting the practice of trying to make the mercury pass through the diseased glands, Mr. Hunter rather contradicts himself in another page, where he confesses his own doubts of its utility in suppurated buboes. However, he admits that mercury alone is not always capable of effecting the cure of such buboes as are deemed venereal; and when the inflammation rises very high, he approves of bleeding, purging, and fomentations. When the inflammation is

erysipelatous, he has a high opinion of bark; and when it is scrofulous, he praises hemlock and poultices made with sea-water. He was also aware of the fact of emetics sometimes occasioning the absorption of the matter of buboes, after it is distinctly formed.

If there is generally great difficulty in pronouncing at first the nature of a primary sore, as to the question of its being syphilitic or not, the same difficulty must occur with respect to judging of the glandular swellings excited by it: and on this account, and from the encouraging circumstances that all buboes may be cured without mercury, and that the course of the venereal disease, unresisted by that mineral, is not so terrible and incurable as used to be supposed, some surgeons, instead of having immediate recourse to mercury, prefer a little delay, in order to see whether the swelling will subside or not under the use of common antiphlogistic means. Thus Dr. Hennen disapproves of using mercury immediately a bubo presents itself; and he states, that the same principles which guide him in the primary ulcers, would have the same, if not greater, force in the case of buboes. "In their irritable state (says he) I consider mercury altogether inadmissible."—(*On Military Surgery, ed.* 2, *p.* 518.)

Although the correctness of some of the principles by which Mr. Hunter regulated his practice in buboes must now be questionable, inasmuch as he calculates too much on the absolute necessity for mercury, and on the usefulness of making it pass through the diseased glands, I conceive that some of his directions are yet too important to be excluded from this work. He says, the quantity of mercury necessary for the resolution of a bubo, must be proportioned to the obstinacy of the complaint; but that *care must be taken not to extend the employment of the medicine so far as to produce certain effects on the constitution.* When the bubo is in a situation which admits of a large quantity of mercury being rubbed in, so as to pass through the swelling, and when the complaint readily yields to the use of half a drachm of mercurial ointment every night, the mouth not becoming sore, or, at most, only tender, Mr. Hunter thinks it sufficient to pursue this course till the gland is reduced to its natural size. In this manner, the constitution will probably be safe, provided the chancre which may have caused the bubo heal at the same time. When the mouth is not affected in six or eight days, and the gland does not readily resolve, then two scruples or a drachm may be applied every night; and, continues Mr. Hunter, if there should still be no amendment, even more must be rubbed in. In short (says he), if the reduction is obstinate, the mercury must be pushed as far as can be done *without a salivation.*

When there is a bubo on each side, so much mercury cannot be made to pass through each, as the constitution in general will not bear this method. However, Mr. Hunter sanctions the plan of minding the soreness of the mouth less in this kind of case; though he adds, that *it is better to let the buboes proceed to suppuration, than to load the system with too much mercury.*

When the situation of buboes will not allow an adequate quantity of absorbed mercury to pass through them, the frictions must be continued in order to affect the constitution; but according to Mr. Hunter, in this case, more mercury will be requisite, than when the remedy can be made to pass directly through the diseased gland; an assertion which may now be doubted.

Many buboes remain without either coming to resolution or suppuration; and, notwithstanding every attempt to promote these changes, the glands become hard and scirrhous. Mr. Hunter conceived, that these cases are either scrofulous at first, or become so as soon as the venereal disposition is removed. He advises the use of hemlock, sea-water, poultices, and sea-bathing.

According to a modern surgeon of judgment and considerable experience, when buboes are in a chronic, stationary state, the application of blisters to the swelling is attended with the most beneficial effects. And he rightly observes, that when such tumours are extremely hard and indolent, it is more advantageous to let the patient have the benefit of the open air, exercise, and his accustomed mode of living, than to confine him in an hospital.—(*Assalini, in Manuale di Chirurgia, p.* 64; *Milano*, 1812.) Stimulating the skin with the antimonial ointment is also sometimes a good practice.

The suppuration of buboes frequently cannot be prevented by any known means. They are then to be treated in some respects like any other abscess. Before opening buboes, Mr. Hunter conceived it advantageous to let the skin become as thin as possible, because a large opening would then be unnecessary, and no measures requisite for keeping the skin from closing, before the bottom of the sore had healed.

Mr. Hunter was doubtful, whether the application of mercury should be continued through the whole suppuration. He was inclined to continue it; but in a smaller quantity.

There has been much dispute whether a bubo should be opened or allowed to burst of itself, and whether the opening should be made with a cutting instrument or caustic. On this subject Mr. Hunter remarks, that there is no peculiarity in a venereal abscess, to make one practice more eligible than another. The surgeon, he says, should be guided in some degree by the patient. Some patients are afraid of caustic; others, of cutting instruments. But when the surgeon has the choice, Mr. Hunter expresses a preference to opening the bubo with a lancet, in which method no skin is lost. But he observes, that when a bubo is very large, and there will be a great deal of loose skin after the discharge of the matter, he thinks that caustic may perhaps be better, as it will destroy some of the redundant skin, and occasion less inflammation than what is caused by an incision. The potassa cum calce is the caustic commonly employed.

After the bubo has been opened, surgeons usually poultice it as long as the discharge and inflammation are considerable, and then they employ dressings, which must be of a quality adapted to circumstances. In the mean while, mercury is continued, both to make the bubo heal, and prevent the bad effects, which might otherwise arise from the matter being continually absorbed.

The mercurial course is to be pursued till the sore is no longer venereal. But in general, since this point is difficult to ascertain, Mr. Hunter advises the continuance of mercury till the part has healed, and even somewhat longer, if the bubo has healed very quickly; for the constitution is apt to become contaminated. However, he did not approve of this long use of mercury in all cases; because buboes often assume, besides the venereal, other dispositions, which mercury cannot cure, and will even exasperate.

Sometimes the sores, when they are losing, or entirely deprived of the venereal disposition, become changed into ulcers of another kind, and most probably of various kinds. How far it is a disease arising from a venereal taint, and the effects of a mercurial course jointly, says Mr. Hunter, is not certain. He suspected, however, that the nature of the part or constitution had a principal share in the case; and, I believe, few surgeons of the present time entertain any doubt of the abuse of mercury being a very frequent cause, independently of any other circumstance.—(See *Mathias on the Mercurial Disease, ed.* 8.)

Mr. Hunter observes, that such diseases make the cure of the venereal affection much more uncertain, because when the sore becomes stationary, or the mercury begins to disagree, we are ready to suspect that the virus is gone; but this (he supposes) is not always the case. He had seen some buboes exceedingly painful and tender to almost every thing that touched them, and the more mild the dressings were, the more painful the parts became.

In some instances the skin alone becomes diseased. The ulceration spreads to the surrounding integuments, while a new skin forms in the centre, and keeps pace with the ulceration, so that an irregular sore, which Mr Hunter compares with a worm-eaten groove, is formed all round. It appears only to have the power of contaminating the parts which have not yet been affected; and those which have, readily heal. According to the same author, when buboes become stationary, and are little inclined to spread, attended with a sinus or two, hemlock, joined with bark, is the medicine most frequently serviceable. It is to be used both externally and internally. Mr. Hunter also speaks favourably of sarsaparilla, sea-bathing, and sea-water poultices. He states, that at the Lock Hospital, gold-refiners' water has been found a useful application: and that, in some cases, benefit has arisen from drinking large quantities of orange juice, and from the use of mezereon.

Lues Venerea.—Surgeons imply, that a *lues venerea* has taken place, when the venereal virus has been absorbed into the circulation. Mr. Hunter does not think the epithet *constitutional* strictly proper in its application to this form of the venereal disease. By *constitutional* disease, he observes, he should understand that in which every part of the body is acting in one way, as in fevers of all kinds; but the venereal poison seems to be only diffused through the circulating fluids, and, as it were, to force certain parts of the body to assume the venereal action, which action is perfectly local. To use Mr. Hunter's phrase, it takes place in different parts in a regular succession of susceptibilities. Only a few parts are acting at the same time; and a person may be constitutionally affected in this way, and yet almost every function may be perfect.

The venereal poison is generally conveyed into the system from a chancre. It may also, according to Mr. Hunter's doctrine, be absorbed from a gonorrhœa. There is likewise a possibility of its getting into the circulation from the surface of the body, without any previous ulceration. According to his doctrine, it may be absorbed from common ulcers, *without necessarily rendering them venereal*; and it may be taken up from wounds, in which cases it generally first causes ulceration.

Venereal Ulcers.—In consequence of the blood being contaminated with real venereal pus, it might be expected that the local effects thus produced would be similar in their nature to those producing them. Mr. Hunter believed that this is not the case. He notices, that the local effects from a constitutional contamination are all of one kind, viz. ulcers, let the effects make their appearance on any surface whatever, either the throat or common skin. But Mr. Hunter conceived, that if the matter, when in the constitution, were to act upon the same specific principles as that which is externally applied, a gonorrhœa would arise when it affected a canal, and only sores or chancres when it attacked other surfaces.

Mr. Hunter found, that even the sores which are caused in the throat are very different from chancres. He says that the true chancre produces considerable inflammation, often attended with a great deal of pain, and quickly followed by suppuration. But the local effects arising from the virus in the constitution, are slow in their progress, attended with little inflammation, and are seldom or never painful, except in particular parts. However, Mr. Hunter allows that this sluggishness in the effects of the poison, depends on the nature of the parts diseased; and he owns, that when the tonsils, uvula, or nose are affected, the progress of the morbid mischief is rapid, and bears a greater resemblance to a chancre than when it occurs on the skin. Even in those parts, Mr. Hunter thought, that the ulcers were attended with less inflammation than chancres which were spreading with equal celerity.

Before the time of Mr. Hunter, the matter secreted by sores which arise from a constitutional infection, was always considered to be of a poisonous quality, like the matter of a chancre. At first, one would expect that this must actually be the case, because venereal matter is the cause, and mercury cures chancres, and also ulcers proceeding from a lues venerea. Mr. Hunter remarks, however, that the latter circumstance is not a decisive proof, since *mercury is capable of curing many diseases besides the venereal.* He also takes notice, that when pus is absorbed from a chancre, it generally produces a bubo; but that a bubo is never occasioned by the absorption of matter from a venereal sore arising from the virus diffused in the circulation. For instance, when there is a venereal ulcer in the throat, no buboes occur in the glands of the neck; when there are syphilitic sores on the arms, or even suppurating nodes of the ulna, no swellings form in the glands of the armpit, although these complaints occur when fresh venereal matter is applied to a common sore on the arm, hand, or fingers. No swelling is produced in the groin in consequence of nodes, or blotches on the legs and thighs.

Some very important experiments are related in Mr. Hunter's *Treatise on the Venereal Disease*, in order to prove that the matter from a gonorrhœa, or chancre, is capable of affecting a man locally, who is already labouring under a lues venerea, and that the matter from secondary syphilitic sores has not the same power. The particulars, however, are too long to be inserted in this book

Parts most susceptible of the Lues Venerea, &c.—Some parts of the body seem to be much less susceptible of lues venerea than others: indeed, Mr Hunter observes, that, as far as our knowledge extends, certain parts cannot be affected at all. The brain, heart, stomach, liver, kidneys, and several other viscera, have never been known to be attacked by syphilis.

The first order of parts, or those which become affected in the early stage of lues venerea, are, the skin, tonsils, nose, throat, inside of the mouth, and sometimes the tongue.

The second order of parts, or those which are affected at a later period, are, the periosteum, fasciæ, and bones.

Mr. Hunter conceived, that one great reason for the superficial parts of the body suffering the effects of the lues venerea sooner than the deep-seated ones, depends on the former being more exposed to external cold. He remarked, that even the second order of parts do not all become diseased at the same time, nor every where at once. But, on the contrary, such as are nearest the external surface of the body are first diseased, as, for instance, the periosteum, bones of the head, the tibia, ulna, bones of the nose, &c. Neither does the disease affect these bones equally on all sides; but first on that side which is next to the external surface. It was Mr. Hunter's belief, however, that the susceptibility of particular bones did not altogether depend upon their nearness to the skin; but upon this circumstance and their hardness together.

The foregoing account by no means agrees with the results of modern inquiries into the nature of the venereal disease; for unless mercury be given, it appears that the bones are very seldom affected by it. Thus, in the cases which were treated by Mr. Rose without mercury, he observes, that "the constitutional symptoms were evidently not such as could be regarded as venereal, if we give credit to the commonly received ideas on the subject. Caries of the bones, and some of the least equivocal symptoms, did not occur. In no instance was there that uniform progress, with unrelenting fury, from one order of symptoms and parts affected to another, which is considered as an essential characteristic of true syphilis."—(*Med. Chir. Trans. vol.* 8, *p.* 423.) We learn also from Mr. Guthrie, that the bones were not affected in any of the cases cured entirely without mercury in the York Hospital, though there were several other cases admitted, "in which a few mercurial pills had been taken, and the mouth not affected, and in which the primary symptoms were followed by eruptions, both papular and scaly, by ulcers in the throat, *by nodes*, and, in one case, by inflammation of the periosteum covering the bones, and ulceration of the septum nasi, although mercury was resorted to for its cure."—(*Vol. cit. p.* 560.) The late Sir Patrick M'Gregor, however, informed me of one or two cases, in which a node took pace, though no mercury had been used. The occurrence, at all events, seems to be rare.

In the examples treated without mercury, under the superintendence of Dr. Hennen, this gentleman did not see "a single case *in which the bones of the nose were affected:* some cases of periostitis, and of pains and swellings of the bones of the cranium and extremities, were met with; but, except in two, he never remarked any nodes which could be regarded as *unequivocally syphilitic.*" One of these yielded to blisters and sarsaparilla; the other, after resisting guaiacum and sudorifics, was dispersed by mercury.—(*On Military Surgery, ed.* 2, *p.* 581.) Dr. Hennen's statement on this subject would have been more satisfactory, had it comprised his opinion of the characters of an unequivocally syphilitic node. On the whole, it appears tolerably certain that mercury, especially when employed unmercifully, and even when employed in moderation, and the patient exposes himself to damp and cold, tends to promote the frequency of nodes, as a sequel of the venereal disease; though as the long and abundant use of the same mineral does not cause the same consequence after other complaints, and venereal ulcers, treated altogether without mercury, rarely lead to nodes, it would seem as if these swellings were the product of the combined action of syphilis and mercury together. The infrequency of nodes in the strictly non-mercurial practice, is one of the most important facts yet established in its favour, and it is curious to find, from some quotations made by Dr. Hennen, that it was well known in former days. Fallopius, in his 90th chap. *De Ossium Corruptione*, speaking of the

loss of the bones of the nose and palate, says, "Et sciatis quod non in omni inveterato gallico hoc fit, sed *tantum in illis, in quibus inunctio facta est cum hydrargyro.*" And Fernelius, in speaking of the injurious effects of mercury, observes, "Recidiva raro similis est radici neque iisdem symptomatis exercet, sed fere distillatione, arthritide tophis, vel ossium carie."—(*Aphrodisiacus, vol.* 3, *p.* 146.) And Palmarius, in considering the affection of the bones, as Dr. Hennen has noticed, uses the following remarkable words: "Sed hoc iis duntaxat contingit, qui olim a lue venerea hydrargyrosi vindicati putarentur, non qui decocto guaiacino et alexipharmaco curati fuissent."—(*De Morb. Contagiosis, cap.* 7, *lib.* 2, *p.* 124; *Parisiis*, 1578.) Dr. Hennen expresses his own conviction, in which I entirely agree, that the carious affections of the bones which are so common in persons treated by long mercurial courses, proceed, not from the disease, but from the remedy rapidly and irregularly thrown in while periostitis exists: and he has not seen a single case of carious bone in the military hospitals since the non-mercurial treatment was adopted, *except where mercury had formerly been used.*—(*On Military Surgery, ed.* 2, *p.* 505, 506.)

Nor will the results of modern experience and inquiries, made on a very extensive and impartial scale, allow us to consider the venereal disease as regularly and unavoidably leading to any secondary symptoms, even though no medicine at all be employed for their prevention. This is fully exemplified in the official reports of the army hospitals. The particulars of 5000 cases, spoken of by Sir James M'Grigor and Sir W. Franklin, lead to the opinion, that "the frequency or rarity of secondary symptoms would seem to depend on circumstances not yet sufficiently understood or explained, although the following fact would tend to the belief, that either the constitutions of the men, or the mode of conducting the treatment without mercury, are the causes that possess the greatest influence in their production. In one regiment, four secondary cases out of 24, treated without mercury, supervened." In another regiment, 68 cases were treated without mercury, all bearing marks of the true venereal disease (and 28 of them especially selected for their decided characters of chancre), yet no secondary symptoms of any kind had taken place fifteen months after the treatment had ceased. The same document, founded on the above large number of cases, confirms another fact, that no peculiar secondary symptoms follow peculiar primary symptoms; a conclusion which is directly adverse to Mr. Carmichael's opinions, of which I have taken more notice in another work.—(See *First Lines of the Practice of Surgery, ed.* 5.)

According to Mr. Hunter, the time necessary for the appearance or production of the local effects in parts most susceptible of the disease, after the virus has passed into the constitution, is generally about six weeks; but in many cases the period is much longer; while in other instances it is shorter. Sometimes the local effects make their appearance within a fortnight after the possibility of absorption.

The effects on other parts of the body which are less susceptible of the venereal irritation, or slower in their action, says Mr. Hunter, are much later in making their appearance. And when the first and second order of parts are both contaminated, the effects generally do not begin to appear in the latter till after a considerable time, and sometimes not till those affecting the former parts have been cured.

Mr. Hunter, however, refers to instances in which the periosteum or bone was affected before any of the first order of parts; but he was uncertain whether the skin or throat would afterward have become diseased, as the disorder was not allowed to go on.

According to Delpech, the principal morbid effects produced on the bones by syphilis, are periostoses, exostoses, and necrosis. As for caries, which has been commonly set down as a consequence of the disease, he says, that authors have generally mistaken necrosis for it; and that the pretended examples of caries of the bones of the nose and palate are in fact more or less extensive denudations and mortifications of the maxillary and turbinated bones, the septum nasi, &c. —(See *Chir. Clin. t.* 1, *p.* 355.)

Venereal Eruptions.—The whole tenor of various facts, specified in the foregoing columns, tends to prove that what is usually called the venereal disease, is in reality several diseases modified also by constitution, climate, regimen, and mode of treatment. And hence, perhaps, the chief source of all the perplexity and uncertainty which are yet so manifest, as fully to justify the doubt sometimes entertained, whether any disease, corresponding to the former notions of syphilis, really exists. Were any proof of the truth of this reflection needed, in addition to the many other proofs of it already premised, the subject of venereal eruptions would at once furnish it; for here no kind of regularity can be traced, neither in the appearances on the skin abstractedly considered, nor in the connexion between certain kinds of primary ulcers and particular forms of cutaneous disease. Nay, as I have noticed in the preceding pages, sometimes, in consequence of a primary venereal sore, different kinds of eruptions form together or successively on one individual; and, as far as one can judge by the eye, exactly the same kind of chancre may produce very different eruptions in different persons, even though treated on precisely the same plan. These circumstances are truly confusing. In Mr. Rose's paper, however, there is a partial confirmation of one part of Mr. Carmichael's theory, viz. the frequency of papular eruptions after simple primary ulcers, or superficial sores, which readily heal. According to the latter gentleman, this form of eruption may also follow gonorrhœa, and is generally preceded by fever, and ends in desquamation. Whatever may be the degree of truth respecting the relation between this kind of eruption and the alleged primary complaints, the practice recommended by Mr. Carmichael for such cases is judicious. General blood-letting is recommended when there is fever, and the medicines praised are antimonials and sarsaparilla. Afterward, when the fever subsides, and the eruption desquamates, an alterative course of antimony and calomel, it is said, will accelerate the cure, though *not absolutely* necessary. In cases of venereal pustular eruptions, supposed by Mr. Carmichael to be most frequent after chancres with elevated edges, without induration, blood-letting is also advised during the febrile stage, followed by antimonials, sarsaparilla, guaiacum, tar-ointment, baths of sulphurated potassa, or the nitro-muriatic bath; and after the pustules have terminated in scaly blotches, alterative doses of mercury, conjoined with sarsaparilla or guaiacum. An eruption of tubercles, or spots of a pustular tendency, or of both intermixed, preceded by fever, and terminating in ulcers covered with thick crusts, complaints which Mr. Carmichael considers a sequel rather of the phagedenic than other chancres, he treats at first by blood-letting, followed by antimonials, sarsaparilla, guaiacum, compound powder of ipecacuanha, arseniate of potassa, nitrous acid, and nitro-muriatic bath. Mercury is said to be hurtful except in the last stage. To scaly blotches, which he conceives to be a sequel of the true chancre or callous ulcer, he applies the same local treatment as to pustular eruptions, and he deems the question, whether sarsaparilla and guaiacum might here be substituted for mercury, yet unsettled.—(See *Obs. on the Symptoms, &c. of Venereal Diseases, Synopsis, p.* 205, &c.) The investigations made in the military hospitals decidedly prove, that all kinds of eruptions, supposed to be venereal, may be cured without mercury; but, I believe, the great and superior usefulness of moderate quantities of mercury, for the removal of the scaly, copper-coloured blotches, is still generally acknowledged. But even in these cases of copper-coloured spots, Mr. Bacot's advice may be good, viz. when the general health is much deranged, the tongue loaded and furred, and the appetite gone, to defer mercury "until, by proper evacuations and attention to the general health," the patient has had the benefit of a delay, "which will, in many instances, render all farther medical treatment unnecessary. It is undoubtedly true, that whatever plan be pursued, these eruptive symptoms will eventually disappear; still, where they continue to linger for a long time, and are attended with their usual accompaniments of great languor, debility, and disturbed rest, I neither know, nor can I understand, the advantage of delaying that remedy which repeated experience has taught me to rely upon," &c.—(*Bacot on Syphilis, p.* 99.) Although Mr. Carmichael's practice seems good, his theory about the connexion of certain sores with particular eruptions and other peculiar secondary symptoms, appears to be nearly refuted by the late investigations made in

the military hospitals. To some facts relating to this question I have already adverted.

There is as little certainty about the essential characters of syphilitic eruptions, as about the test of every other symptom of the venereal disease or rather diseases. While Mr. Hunter describes the eruption as generally occurring over the whole body, Dr. Bateman states, that syphilitic affections of the skin commonly make their first appearance on the face, where they are usually copious, and on the hands and wrists.—(*Pract. Synopsis of Cutaneous Diseases*, *p.* 332, *ed.* 3.) Their colour, he says, is in general less livid than that of ordinary eruptions, being of a brownish-red of different shades; but that this is not universal; for some of the syphilitic ecthymata have a bright red base in the beginning. Exposure to cold accelerates their progress and increases their extent; while, on the other hand, warmth retards and ameliorates them.—(*P.* 333.) According to Hunter, the discolorations make the skin appear mottled, and *many of the eruptions disappear*, while others continue and increase with the disease.

In other cases, the eruption comes on in distinct blotches, which are often not observed till the scurf has begun to form. At other times, the eruption assumes the appearance of small distinct inflammations, containing matter and resembling pimples, not being, however, so pyramidal nor so red at the base. Mr. Hunter also observes, that venereal blotches, on their first coming out, are often attended with inflammation, which gives them a degree of transparency which is generally greater in the summer than the winter, especially if the patient be kept warm. In a little time, this inflammation disappears, and the cuticle peels off in the form of a scurf. The latter occurrence often misleads the patient and the surgeon, who look upon this dying away of the inflammation as a decay of the disease, till a succession of scurfs undeceives them.

The parts affected next begin to form a copper-coloured, dry, inelastic cuticle, called a scurf or scale. This is thrown off and new ones are formed, which spread to the breadth of a sixpence or shilling; but seldom more extensively, at least for a considerable time. In the mean while, every succeeding scale becomes thicker and thicker till at last it becomes a common scab. Then the disposition for the formation of the matter takes place in the cutis underneath, and a true ulcer is produced, which commonly spreads, although in a slow way.

When the affected part of the skin is opposed by another portion of skin, which keeps it in some degree more moist, as between the nates, about the arms, between the scrotum and the thigh, in the angle between the two thighs, on the red part of the lip, or in the armpits, the eruptions, instead of being attended with scurfs and scabs, are accompanied with an elevation of the skin, which is swollen with extravasated lymph into a white, soft, moist, flat surface, which discharges a white matter.—(*Hunter.*)

Sir Anthony Carlisle has pointed out what he terms an herpetic abrasion of the cuticle on the breast or abdomen, having the appearance of venereal blotches. He states that it is less deep in the skin; that it has ess of an inflammatory base; and that it is not so dis- nctly circumscribed as the true venereal blotch. It never forms a purulent crust; but is simply a furfuraceous scaling of the cuticle. This form of disease seems to him to be produced by a disordered stomach and liver.—(See *Lond. Med. Reposit. vol.* 7, *p.* 92.)

A venereal eruption often attacks that part of the fingers on which the nail is formed. Here the disease renders the surface red, which is seen shining through the nail; and if allowed to continue, a separation of the nail takes place.

When surfaces of the body covered with hair are attacked, the hair separates, and cannot be reproduced as long as the disease lasts.

Mr. Welbank describes the true syphilitic eruption, as consisting of firm and slightly elevated spots, from which pellicles or scales are *from the commencement* successively detached. These spots are thick about the scalp, chin, forehead, and upper and inner part of the thighs. Where there is hair, they frequently form slightly elevated crusts of a pale colour. On the palms of the hands, or soles of the feet, they are characterized by a thick, honeycomb desquamation of the dense cuticle. They are more disposed to superficial ulceration, when confluent, or situated between opposed and secreting surfaces, as the angles of the mouth, scrotum, and thigh, &c.—(See *Med. Chir. Trans. vol.* 13, *p.* 569.)

It must be allowed, that it is frequently very difficult to say, whether an eruption is syphilitic or not, and an opinion should rather be formed from the history of the case than from any particular appearance of the eruption itself. As Dr. Bateman has remarked, the cutaneous eruptions, which are the result of the venereal poison, are often the source of considerable embarrassment to the practitioner. They assume such a variety of forms, that they bid defiance to any arrangement founded upon their external character; and, in fact, they possess no common or exclusive marks, by which their nature and origin are indicated. There is, perhaps, no order of cutaneous appearances, and scarcely any genus or species of the chronic eruptions, which these secondary symptoms of syphilis do not occasionally resemble. Dr. Bateman admits, however, that, in many cases, there is a difference, which a practised eye will recognise, between the ordinary diseases of the skin and the syphilitic eruptions, to which the same generic appellation might be given. This, says he, is often observable *in the shade of colour, in the situation occupied by the eruption, in the mode of its distribution, and in the general complexion* of the patient. Hence, to a person conversant with those ordinary diseases, a degree of anomaly in these respects will immediately excite a suspicion, which will lead him to investigate the history of the progress of such an eruption, and of its concomitant symptoms.—(See *Bateman's Practical Synopsis of Cutaneous Diseases*, *p.* 331, 332, *edit.* 3.)

Dr. Hennen does not pretend to be able to discriminate the true syphilitic eruptions from others, and, indeed, by what criterion they are to be known, I am myself entirely puzzled to comprehend, after the numerous facts so fully established by recent experimental inquiries. Dr. Hennen generally approves of deferring the use of mercury at first, in order to see whether these cutaneous affections will yield to other means; "but (says he) I should not very long postpone the employment of the mildest mercurial alteratives, aided by warm bathing and sudorifics."—(*On Military Surgery*, *ed.* 2, *p.* 518.)

Venereal Disease of the Throat, Mouth, and Tongue.—In the throat, tonsils, and inside of the mouth, the disease is said by Mr. Hunter generally to make its appearance at once in the form of an ulcer, without much previous tumefaction. Consequently, the tonsils are not much enlarged.

A venereal ulcer in the throat was supposed, by the same author, to be in general tolerably well marked, though he confesses, that it may not in every instance be distinguished from an ulcer of a different nature. Several diseases of the throat, he remarks, do not produce ulceration on the surface. One is common inflammation of the tonsils. The inflamed place often suppurates in the centre, so as to form an abscess, which bursts by a small opening; but never looks like an ulcer that has begun superficially, like a true venereal sore. The case is always attended with too much inflammation, pain, and tumefaction of the parts to be venereal. Also, when it suppurates and bursts, it subsides directly, and it is generally attended with other inflammatory symptoms in the constitution.

Mr. Hunter then notices an indolent tumefaction of the tonsils, peculiar to many persons, whose constitutions are disposed to scrofula. The complaint produces a thickness in the speech. Sometimes coagulable lymph is thrown out on the surface of the parts affected, and occasions appearances which are by some called ulcers; by some, sloughs; and by others, putrid sore throats. The case is attended with too much swelling to be venereal, and, with a little care, it may easily be distinguished from an ulcer or loss of substance. However, when this difference is not obvious at first sight, it is proper to endeavour to remove some of the lymph, and, if the surface of the tonsil underneath should appear to be free from ulceration, we may conclude with certainty that the disease is not venereal. Mr. Hunter states, that he has seen a chink filled with coagulable lymph, so as to appear very much like an ulcer; but, on removing that substance, the tonsil underneath was found perfectly sound. He adds, that he has seen cases of a swelled tonsil having a slough in its centre, which slough, before its detachment, looked

very like a foul ulcer. The stage of the complaint, he says, is even more puzzling when the slough has come out; for then the disease has most of the characters of the venereal ulcer. Whenever he met with the disease in its first stage, he always treated it as if it had been of the nature of erysipelas, or a carbuncle. When the complaint is in its second stage, without any preceding local symptoms, he recommends the practitioner to suspend his judgment, and to wait a little, in order to see how far nature is able to relieve itself. If there should have been any preceding fever, the case is still less likely to be venereal. Mr. Hunter informs us, that he has seen a sore throat of this kind mistaken for a venereal case, and mercury given until it affected the mouth, when the medicine brought on a mortification of all the parts concerned in the first disease.

Another complaint of these parts, which Mr. Hunter epresents as being often taken for a venereal one, is an ulcerous excoriation, which runs along their surface, becoming very broad and sometimes foul, having a regular termination, but never going deeply into the substance of the parts, as Mr. Hunter believes the venereal ulcer does. No part of the inside of the mouth is exempt from this ulcerous excoriation; but, according to Mr. Hunter, the disease most frequently occurs about the root of the uvula, and spreads forwards along the palatum molle. He remarks, that the complaint is evidently not venereal, *since it does not yield to mercury.* He has seen these ulcerous excoriations continue for weeks, without undergoing any change, and a true venereal ulcer make its appearance on the surface of the excoriated part. He says that such excoriations were cured by bark, after the end of the mercurial course, by which the syphilitic sore was cured.

This author describes the true venereal ulcer in the throat, *as a fair loss of substance, part being dug out,* as it were, *from the body of the tonsil: it has a determinate* edge, and *is* commonly *very foul, having thick white matter, like a slough, adhering to it,* and not admitting of being washed away.

According to the experience of one late writer, the ulceration of the tonsil is attended with little pain at first, and excavates the part deeply, and often in a triangular form, as if the tonsil were split. It slowly acquires a smooth bluffy surface.—(*Welbank, in Med. Chir. Trans. vol.* 13, *p.* 569.)

Here, however, as in most other supposed forms of syphilis, some test is wanting, by which the case may be certainly distinguished from other diseases of the throat presenting similar appearances: for, as Mr. Rose has very truly remarked, "the excavated ulcer of the tonsils, as described by Mr. Hunter, is not, as Mr. Carmichael seems to think, a peculiar symptom of the presence of the syphilitic virus. I have repeatedly seen it, as well as the scaly blotch, in cases where mercury had been freely employed for the primary sores, and in which I considered the virus as eradicated; and both have disappeared under the use of sarsaparilla." —(*Med. Chir. Trans. vol.* 8, *p.* 421.) In a recent work, Mr. Carmichael himself acknowledges the justice of the preceding observation, and owns that since the publication of his Essays, he has often noticed the excavated ulcer of the tonsils, either attending the primary phagedenic ulcer or the train of constitutional symptoms which arise from it.—(*On the Symptoms, &c. of Venereal Diseases, p.* 17.) In affections of the throat, Dr. Hennen states, that he "would be more guarded than in any others in the employment of mercury, until all inflammatory disposition was removed." Afterward he has seen them yield, "as if by magic, so soon as the local effects of mercury on the parts within the mouth became obvious." But, when mercury was given earlier, he has seen a vast number of instances in which irremediable mischief was done.—(*On Military Surgery, ed.* 2, *p.* 518.)

According to Hunter, lues venerea sometimes produces a thickening and hardening of the tongue, but frequently ulceration, as in other parts of the mouth. He describes venereal sores on the tongue as generally more painful than those on the skin; but less so than common sore throats from inflamed tonsils. They oblige the patient to speak thick, as if his tongue were too large for his mouth, with a small degree of snuffling.

Mr. Hunter doubted the reality of a venereal ophthalmy; but, that one form of iritis is of this nature, is at present a fact universally admitted. See the subject of iritis, in the article *Ophthalmy.*

Symptoms of the second stage of Lues Venerea.—The periosteum, fasciæ, tendons, ligaments, and bones are the parts which Mr. Hunter enumerates as liable to be affected in the second stage of lues venerea. This observation in its full extent, however, seems to be rendered rather questionable; for it would appear from the evidence both of ancient and modern writers, that *true nodes* or *venereal swellings of the bones, and particularly caries, rarely take place from syphilis, unless mercury be employed.* It is an observation of Mr. Hunter's, that we cannot always know with certainty what parts may become affected in this stage of the disease. He says he has known the distemper produce a total deafness, sometimes followed by suppuration, and great pain in the ear and side of the head. I have already explained, that it was one of this gentleman's doctrines, that the second order of parts was generally deep-seated. When these become irritated by the poison, he observes, that the progress of the disease is more gradual than in the first order of parts. It assumes very much the character of scrofulous swellings, or chronic rheumatism; only it affects the joints less frequently than the latter affection does. A swelling sometimes makes its appearance on a bone, when there has been no possible means of catching the infection for many months; and, in consequence of the little pain experienced, the tumour may be of considerable size before it is noticed. Sometimes a great deal of pain is felt; but no swelling comes on till after a long while. According to Mr. Hunter, these remarks are also applicable to swellings of the tendons and fasciæ. As tumours of this kind only increase by slow degrees, they are not attended with symptoms of much inflammation. When they attack the periosteum, they seem like an enlargement of the bone itself, in consequence of being very firm, and closely connected with the latter part. Mr. Hunter also farther observes, that, in these advanced stages of the disease, the inflammation can hardly get beyond the adhesive kind, in which state it continues to become worse and worse, and when matter is formed it is not true pus, but of a slimy description. Some nodes, he says, both of the tendons and bones, last for years, before they form any matter at all. *These cases* he considered *as not being certainly venereal,* though commonly considered as such. Mr. Hunter found it difficult to explain the reason, why, when lues venerea attacks the bones, or the periosteum, the pain should sometimes be considerable, and sometimes very trivial. Venereal pains in the bones are described by Mr. Hunter as being of a periodical kind, generally most severe in the night-time.

At the present day, when many cases formerly supposed to be syphilitic are treated without any mercury, and even those which are reputed to be venereal are cured by much smaller doses of that medicine than were given in Mr. Hunter's time, nodes have become much less frequent; and I have already, in a previous part of this article, expressed my decided belief in the justness of the opinion given by Fallopius and others, that a disposition to nodes is often occasioned by the abuse of mercury.

Treatment of Lues Venerea.—In Mr. Hunter's opinion, the first order of parts, or those which are most susceptible of being affected in lues venerea, are also the most easy of cure; while the second order of parts takes more time to be remedied.

In the class of complaints arising in the second stage of the lues venerea, Mr. Hunter believed that it was unnecessary to continue the employment of mercury till all the swelling had disappeared. For it is observed by this distinguished writer, that, since these local complaints cannot contaminate the constitution by reabsorption, and since the venereal disposition and action from the constitution can be cured while the local effects still remain, and this even when the tumefaction, forming nodes on the bones, fasciæ, &c has proceeded to suppuration, there can be no occasion for continuing the course after the venereal action has been destroyed. Whatever may be hereafter decided concerning the superiority of mercury as a remedy for many secondary symptoms, one thing appears already well made out, viz. that it should always be employed with moderation, lest it produce worse effects and more terrible diseases than those which it is designed to relieve. For an account of the various ways of exhibiting it, I must refer to the article *Mercury* Delpech adopts the notion, that the primary symptoms

of the venereal disease are most successfully treated by introducing mercury into the system from the surface of the body, and, if possible, partly through the same set of absorbents as first took up the virus; for the cure of secondary symptoms he prefers the blue pill.—(*Chir. Clin. t.* 1.)

To the following ingenious reasoning on the operation of mercury, and the principles by which its administration should be regulated, surgeons of the present day will not give more credit than facts warrant; because some of Mr. Hunter's opinions are manifestly influenced by the supposition that mercury is *absolutely* necessary for the cure of the venereal disease.

In curing the lues venerea, mercury can only have two modes of action; one on the poison, the other on the constitution. If, says Mr. Hunter, mercury acted on the poison only, one might conceive it did so, either by destroying its qualities, by decomposing it, or else by attracting it, and carrying it out of the circulation. If mercury acted in the first of these ways, one would expect that the cure would depend on the quantity of the medicine taken into the system. If it acted in the second manner, one would infer that the progress of the cure would be proportionate to the quantity of evacuation. But, observes Mr. Hunter, if it act upon the principle of destroying the diseased action of the living parts, and of counteracting the venereal irritation by producing one of a different kind, then neither quantity alone nor evacuations will avail much. He states, that the quickness of the cure depends on quantity joined with visible effects. However, it is added, that although the effects which mercury has upon the venereal disease, are in some degree proportioned to the local effects of the medicine on some of the glands or particular parts of the body, as the mouth, skin, kidneys, and intestines, yet such effects are not altogether proportioned to these other circumstances. When mercury disagrees with the constitution, so as to produce great irritability and hectic symptoms, this action of irritation, as Mr. Hunter explains, is not a counter-irritation to the venereal disease.

It was also noticed by the same author, that the effects of mercury on lues venerea are always in proportion to the quantity of the remedy exhibited in a given time, and the susceptibility of the constitution to the mercurial irritation. He says that these circumstances require the most minute attention, and that, in order to obtain the greatest action of mercury with safety, and in the most effectual manner, the medicine must be given till it produces effects somewhere. However, it must not be exhibited too quickly, in order that a sufficient quantity may be given before we are obliged to stop, in consequence of the effects. Mr. Hunter thinks that when the local effects are produced too quickly, they prevent a sufficient quantity of the remedy from being taken into the system to counteract the venereal irritation at large.

Mr. Hunter mentions his having seen some cases in which mercury acted very readily locally, and yet the constitution was hardly affected by it, for the disease would not give way. He states that he has met with other cases, in which the mere quantity of mercury did not answer, till it was given so quickly as to affect the constitution in such a manner as to produce local irritation, and, consequently, sensible evacuations. This, he observes, is a proof that the local effects of mercury are often the sign of its specific effects on the constitution at large, and it shows that the susceptibility of the diseased parts to be affected by the medicine is in proportion to its effects on the mouth. Its effects, he contends, are not to be imputed to evacuation, but to its irritation. Hence he inculcates, that mercury should be given, if possible, in such a manner as to produce sensible effects upon some parts of the body, and in the largest quantity that can be given to produce these effects within certain bounds. Mr. Hunter also remarks, that these sensible effects should be the means of determining how far the medicine may be pushed, so as to have the greatest effect on the disease without endangering the constitution. The practice must vary according to circumstances; and if the disease be in a violent degree, less regard must be had to the constitution, and mercury must be thrown into the system in larger quantities; a very dangerous precept, as far as I can judge from many cases in which I have seen it acted upon.

Mr. Hunter likewise acquaints us, that when the disease is in the first order of parts, a smaller quantity of mercury is necessary than when the second order of the parts is affected and the disease has been of long standing: its first appearances alone being cured, and the venereal disposition still remaining in the secondary parts. For the purpose of curing the venereal disease, whether in the form of chancre, bubo, or lues venerea, Mr. Hunter was of opinion that probably the same quantity of mercury is necessary. He represents that one sore requires as much mercury as fifty sores in the same person, and a small sore as much as a large one. He thought that the only difference, if there is any, must depend upon the nature of the parts affected, that is, on their being naturally active or indolent. He conceived, however, that, on the whole, recent venereal complaints are generally more difficult to cure than the symptoms of lues venerea, and that this may make a difference in regard to the quantity of mercury necessary.

Having now delivered the principal general instructions relative to the exhibition of mercury in the treatment of the venereal disease, as given by Mr. Hunter, I must not quit this subject without remarking that even this eminent surgeon appears on the whole too partial to the long use of mercury, and sometimes to the introduction of immoderate quantities of it into the system. In general, however, his observations tend to condemn all violent salivations. It is to be recollected that, in his days, nobody had a suspicion that truly syphilitic sores (if this expression be allowable, while they cannot be defined nor distinguished by their appearances) would in the end spontaneously heal; and he himself had no dependence upon any medicine except mercury for the cure of the true venereal disease. But modern experience evinces that the disorder seldom now presents itself in forms so bad and intractable as formerly; that it is even capable of spontaneously ceasing: and that we hardly ever see cases in which it is requisite to give mercury, except in very moderate quantities. Indeed, such is the change, that many surgeons suspect that the very nature of the disease must have undergone a material alteration or modification. In England, in my opinion, every thing is to be referred to the improved manner of employing mercury only in moderate doses, and never pushing its exhibition till the constitution is so impaired that indescribable forms of diseases ensue, which are sometimes the compound effect of mercury and syphilis together; and, in other instances, of that description which surgeons now frequently call *syphiloid* or *pseudo-syphilitic*, not depending upon the venereal poison at all, but upon a state of the system, which mercury is known to aggravate in the worst degree. For additional information concerning internal remedies for the venereal disease, see *Mercury*, *Guaiacum*, *Mezereon*, *Muriatic Acid*, *Nitrous Acid*, *Sarsaparilla*, *Sulphuric Acid*, *&c.*

With respect to the local treatment of the symptoms of lues venerea, Mr. Hunter thought that none would in general be necessary, since the constitutional treatment would commonly effect a cure. However, he admits that sometimes the local effects will not give way, and the parts remain swollen in an indolent, inactive state, even after there is every reason to believe that the constitution is perfectly cured. In such cases, he recommends assisting the constitutional treatment by local applications of mercury to the part, either in the form of a plaster or ointment. The latter application, he says, is the best. When these are not sufficient, he advises an attempt to be made to excite inflammation of another kind. He says, *he has seen a venereal node, which gave excruciating pain, cured by merely making an incision down to the bone the whole length of the node. The pain ceased, the swelling decreased, and the sore healed up kindly, without the assistance of a grain of mercury.* He mentions that blisters have been applied to nodes with success, removing the pain and taking away the swelling.

With regard to these last cases, I may add that, for many years past, the idea of completely dispersing nodes by mercury has been entirely abandoned by many of the best practitioners; and at present, long protracted mercurial courses for the cure of such swellings are totally relinquished. When small, moderate quantities of mercury have had their full effect, a blister is applied over the swelling, and kept open; under

which plan the tumour generally subsides, as far as its nature will allow.

Diseases resembling the Venereal. Pseudo-syphilis.—Sores on the glans penis, prepuce, &c., in the form of chancres, as Mr. Hunter notices, may and do arise without any venereal infection; and sometimes they are a consequence of former venereal sores which have been cured.

The symptoms produced by the venereal poison in the constitution, are such as are common to many other diseases. For instance, Mr. Hunter remarks, that blotches on the skin are common to what is called a scorbutic habit; pains are common to rheumatism; swellings of the bones, periosteum, fasciæ, &c. to many bad habits, perhaps, of the scrofulous and rheumatic kind. Thus, says he, *most of the symptoms of the venereal disease, in all its forms, are to be found in many other diseases. Hence, the original cause, and many leading circumstances, such as dates, effects of the disorder upon others, from connexion, when only local, the previous and present symptoms, &c. must be considered, before we can determine absolutely what the disease truly is.* All the circumstances and symptoms taken together may be such as will attend no other disease. However, Mr. Hunter confesses that, with all our knowledge, and with all the application of that knowledge to suspicious symptoms of this disease, *we are often mistaken, calling distempers venereal which are not so, and sometimes supposing really syphilitic affections to be of another nature.*

Mr. Hunter takes notice that, in some constitutions, rheumatism, in many of its symptoms, resembles the lues venerea. The nocturnal pains, swelling of the tendons, ligaments, and periosteum, and pains in those swellings, are symptoms both of the rheumatism and also of the venereal disease, when it attacks such parts. Mr. Hunter, however, did not know that *he had ever seen the lues venerea attack the joints*, though many rheumatic complaints of such parts are cured by mercury, and therefore supposed to be venereal.

Mercury, given without caution, often produces the same symptoms as rheumatism. Such complaints Mr. Hunter had seen mistaken for venereal ones, and mercury continued. He explains that some diseases not only resemble the venereal in appearance, but in the mode of contamination, proving themselves to be poisons by affecting the part of contact; then producing immediate consequences similar to buboes; and also remote consequences similar to the lues venerea.

Mr. Hunter observes, that it is nearly as dangerous in some constitutions to give mercury when the disease is not venereal, as to omit it in other cases which are really syphilitic; and, had he been acquainted with recent investigations, he would undoubtedly have gone farther, and declared that it is in reality far more dangerous. Many of the constitutions which put on some of the venereal symptoms when the disease is not really present, he says, are those with which mercury seldom agrees, and commonly does harm. He had seen mercury which was exhibited for a supposed venereal ulcer of the tonsils, produce a mortification of those glands, and the patient was nearly destroyed. No doubt this was an example of what Mr. Carmichael would call the phagedenic venereal disease.

Mr. Abernethy, in his *Surgical Observations*, 1804, has treated at some length of diseases resembling syphilis, and has adduced several very interesting cases, which I advise every surgical practitioner to read with the greatest attention, as they confirm the views of the subject lately so fully established.

"A gentleman (says he) thought that he had infected a slight cut on his hand (which was situated in front of, and just below, the little finger) with the discharge from a bubo in the groin, that he had occasion to open. The wound fretted out into a sore about the size of a sixpence, which he showed me, and which I affirmed had not the thickened edge and base, and other characters of a venereal chancre. I therefore recommended him to try the effect of local means, and not to use mercury.

In about a month, the sore, which had spread a little, became contracted in its dimensions, and assumed a healing appearance. At this time, pain was felt extending up the arm, and suddenly a considerable tumour rose over the absorbing vessels, which proceed along the inner edge of the biceps muscle. This tumour became nearly as big as a small orange As the original sore seemed now disposed to heal, and as there was no surrounding induration, I could not believe it venereal, and therefore recommended him still to abstain from mercury, and apply leeches and linen moistened in the aq. litharg. acet. comp. to the tumour formed over the inflamed absorbents. For it seemed to me that if the venereal poison had been imbibed from the sore, it would have passed on to one of the axillary glands, and would have caused induration and inflammation to take place there more slowly than had occurred on the present occasion.

Under this treatment the tumour was discussed, and the sore at the same time healed. About three weeks afterward the patient called on me, and said that there were venereal ulcers in his throat; and in each tonsil there was an ulcer deeply excavated, with irregular edges, and with a surface covered by adhering matter; ulcers, in short, which every surgeon who depends on his sight as his guide, would have pronounced to be venereal. Shortly after, also, some copper-coloured eruptions appeared on his face and breast. He showed his disease to several surgeons, on whose opinion he relied, who, without hesitation, affirmed that they were venereal, and that the mercurial course had been improperly delayed.

While the patient was looking out for lodgings, in order that he might go through the mercurial process, a circumscribed thickening and elevation of the pericranium, covering the frontal bone, appeared: it was of the circumference of a half-crown piece; and was, in short, what every surgeon who is guided only by his sight and touch, would, without hesitation, have called a fair corona veneris. I now told the patient that I was more inclined to believe his disease was not syphilitic, from the sudden and simultaneous occurrence of this node with the sore throat, &c. Other surgeons thought differently; and I believe this very sensible and amiable young man imagined that his health would become a sacrifice if he any longer attended to my opinion. He was preparing to submit to a mercurial course, when very important concerns called him instantly into the country. He went with great reluctance, taking with him mercurial ointment, &c.; and after a fortnight I received a letter from him, saying that he found his complaints benefited by his journey, that business had prevented him from beginning the use of mercury for a few days, that he now found it was unnecessary, for his symptoms had almost disappeared; and shortly afterward he became perfectly well."

Mr. Abernethy considers this case as the most unequivocal instance extant of a disease which could not by appearance be distinguished by surgeons of the greatest experience from syphilis, and which, however, was undoubtedly of a different nature (that is to say, it was of a different nature according to certain criteria then generally believed, but which recent investigations have proved to be destitute of foundation). All the tests here alluded to having been spoken of in the foregoing columns, I shall not here repeat them.

Some years ago the nitric acid was introduced as a remedy for syphilis.—(See *Nitrous Acid.*) To the position of its efficacy being as great in venereal cases as was first alleged, many surgeons have not acceded, though, as a sensible writer has observed, it has certainly been allowed, with some other medicines, to remain in a kind of copartnership with mercury, and admitted to be useful in venereal cases under certain circumstances. A great deal of this want of agreement on the effects of remedies in syphilitic cases, is now explained by the imperfection of the diagnosis, and the important fact that the disease may generally be cured in time without any medicines whatsoever, though this time is sometimes long. Dr. Scott, who first suggested the use of nitrous acid, has attempted to account for its alleged occasional failures by observing, that the acid which he employed was not pure nitric acid, but an impure acid, containing an admixture of muriatic acid. He therefore, some time ago, recommended the use of a compound acid, containing three parts of nitric acid, and one of muriatic, which he administered internally, and also applied externally, largely diluted as a bath, until the gums were affected and ptyalism produced; and he conceived every trial as quite inconclusive, unless these constitutional effects occurred.

"The acid that I have used of late (says Dr. Scott)

is the nitro-muriatic; and it is formed by mixing together equal parts of the nitrous or nitric acid and muriatic acid. If these acids be in the state of concentration that they usually possess in the shops, and if the quantities be considerable, a great volume of gas is developed on their coming into contact, which taints every part of a house, is extremely hurtful to the lungs, and disagreeable to the smell. To avoid this inconvenience, I put a quantity of water, at least equal in bulk to both the acids, into a bottle, and I add the acids to it separately. This method does not only prevent the unpleasant odour, but it tends to retain the chlorine, on which its effects depend. It is well known, that the nitro-muriatic acid acts very readily on the metals and earth; nothing, therefore, but glass or extremely well-glazed vessels of porcelain, should be used to contain it. Wooden tubs for bathing answer very well, and they should always be made *as small as possible*, compatible with their holding the body, or the limbs that we wish to expose to the bath. From their being small we save acid, and are able to heat the bath with ease. In India, I have often exposed the whole body below the head to this bath; but here I have been satisfied, in general, with keeping the legs and feet exposed to it. In order to warm the bath after the first time, I have commonly made a third or a fourth part of it be thrown away, and the loss replaced by boiling water and a proportional quantity of acid. To save the expenditure of acid, I have occasionally warmed a portion of the bath in porcelain vessels, placed near the fire, but I fear this may diminish its effects.

It is no easy matter (continues Dr. Scott) to give directions with regard to the degree of acidity of the bath. I have commonly made it about as strong as very weak vinegar, trusting to the taste alone. The strength should be regulated by the degree of irritability of the patient's skin. I may say, that although I like to know that it is strong enough to prick the skin a very little, after being exposed to it from fifteen to thirty minutes, yet I believe that even such an effect as this is unnecessary.

The time too of remaining in the bath in order to produce the greatest effect, is a matter of doubt. I have kept the legs and feet exposed to it for half an hour or more; but with more delicate people, not above one-half or one-third of that time. I have repeated these baths daily, or even twice or thrice a day."—(See *Med. Chir. Trans. vol.* 8, *p.* 181.) Dr. Scott adds, that the mere sponging the skin with nitro-muriatic acid sufficiently diluted with water, gives rise to the very same effects as bathing, and is more easily adopted. Fifteen or twenty minutes may be employed in the sponging, though a much less time produces very material effects.

Dr. Scott has found the nitro-muriatic acid particularly useful even in this country, in that description of syphilis which is termed *pseudo-syphilis;* and he attributes the beneficial effects to the chlorine, which is loosely combined in this compound.—(See *Journal of Science and the Arts, vol.* 1, *p.* 205—211; *Lond. Med. Reposit. vol.* 7, *p.* 59; and *Med. and Chir. Trans. vol.* 8, *p.* 173, *et seq.*)

The only important conclusion which I venture to draw from Dr. Scott's observations is, a confirmation of the fact of the generally curable nature of syphilitic diseases without the aid of mercury. And I farther believe, that though the nitro-muriatic bath may sometimes be useful, the surest way of bringing it into discredit is, to represent it as applicable to all forms of syphilis, for which neither this remedy nor even mercury itself will ever suffice. The muriate of gold has been much commended of late years; but after the facts detailed in this article, the alleged merit of new remedies must be received with suspicion, and in particular the idea of their specific powers rejected.

[The preceding article is an elaborate and, upon the whole, an able exposition of the present state of our knowledge of the venereal disease, though in the existing condition of conflicting opinions concerning the identity of the poison capable of inducing such a variety of results as are to be observed in syphilitic affections, we are yet left in doubt as to some of the most important principles which ought to govern us in our treatment of specific disorders of the genital system. To Mr. Carmichael the profession is in an especial manner indebted for much interesting matter on the subject, and the facts which the more recent occurrence of the disease among the peninsular army has furnished us, are also to be cherished as of great practical utility.—(See *Hennen, Fergusson, Guthrie, &c.*)

The writers on mercury, and on syphilitic complaints, who have appeared in the United States, deserve also to be studied with some care, inasmuch as not a few of them, from ample opportunities, have set forth many interesting views on these intricate questions.—(See *Rousseau in Philadelphia Medical Museum, vol.* 4. *Holyoke, in New-York Medical Repos. vol.* 1. *See in do. vol.* 4. *Rush, in do. vol.* 5. *Ogden, in do. vol.* 5. *Harris, in North Amer. Med. Journal, vol.* 1. *Warren's View of Mercurial Practice, in Mass. Med. Communications. Francis's Dissertation on Mercury. Chapman's Therapeutics, &c.*)

Medical observers of the present day seem to place less confidence in the authoritative opinions of Mr Hunter than formerly, and his doctrine of the identity of the poison of gonorrhœa and syphilis, of his infallible diagnostics of chancre, and, farther, his precept of the necessity of excessive salivation, have probably few advocates in America. Moreover, the latest investigations by British and continental writers seem to have removed the little of partiality that was cherished until recently in behalf of these Hunterian principles.

That gonorrhœa and syphilis originate from distinct poisons, and that moderate salivation only, or the merely subjecting the system to the influence of mercury, is all that is necessary, is, perhaps, maintained by nine-tenths of the intelligent prescribers of this country; and the sweeping anathemas of Mr. John Pearson, of the London Lock Hospital, in relation to the inefficiency of the corrosive sublimate, have been disproved innumerable times by most decided clinical illustration. I shall here insert an extract from an elaborate essay on mercury, by my friend Prof. Francis, written some time since, when the advocates for the corrosive sublimate were not so numerous as at present. The entire paper may be seen in *Hosack's and Francis's American Med. and Philosophical Register, vols.* 3 *and* 4. To the interrogatory, what are the changes effected in the system by the influence of mercury? Dr. F. observes, "Little is indeed known concerning the peculiar nature of the virus of specific diseases; the action which takes place upon the application of the smallest particle of morbific matter to the human body, and the process by which it generates disease, converting a local into a general disorder, and thus producing an altered and vitiated state of the whole system, it must be admitted, are neither very obvious to the senses, nor very clear to the reasoning powers of man. The effects themselves, however, have been long and familiarly known, and, from duly considering these, a rational theory may, perhaps, be formed of the manner in which they are produced.

That the poison of specific diseases, as that of lues venerea, small-pox, &c., diffuses itself through the whole constitution, and assimilates into its own nature the general mass of circulating fluids, seems to be most consonant to all that is understood of their peculiar character. Upon the introduction of a particle of variolous matter into the system, an inflammatory action of the part into which it is inserted is excited; by which action new morbific matter of the same nature is generated. This process may be carried on to a greater or less extent, in a longer or shorter time, in different persons, before the specific material enters the absorbents; and hence local inflammation is in some cases considerably advanced before the system becomes affected, while in others the eruptive symptoms supervene when it appears to have made very little progress. The morbid poison, modified in its action by its degree of acrimony, the condition of the part, and habit of body, is taken up by the absorbents, and enters the blood-vessels, whence it is received into the general circulation, and produces its peculiar effects upon the constitution. The fluids themselves are therefore necessarily first affected, and, as a consequence of their morbid condition, the solids themselves next become vitiated. Hence the multiplication of the matter of variolous contagion in inoculated small-pox; and hence, on the same principle, the generation of morbific matter from a similar action, arising from the introduction of the other specific contagions. By the introduction of a specific morbid matter into the body, its condition is changed from a healthy to a diseased state,

the local is converted into a general disorder; the fluids, and ultimately the solids, become affected, and, according to the peculiar virus introduced, the whole constitution partakes in a greater or less degree of its peculiar nature, whether it be small-pox, lues venerea, measles, &c." The theory of Mr. Hunter, that mercury induces its salutary changes, by creating a new specific action, and that thus it destroys the specific disorder lues venerea, in conformity to the law that no two specific actions can exist at the same time, is shown by Dr. F. to be untenable and unsatisfactory, from the well-known fact, that it often happens that two specific diseases prevail simultaneously in the human constitution; as we find recorded in the cases of Pearson, Jenner, Haygarth, and others in the small-pox, and by other authors on various diseases of an acknowledged specific character.

But the theory of Mr. Hunter is attempted to be overthrown by other facts concerning the changes induced by morbid action, for which I must refer the reader to the essay of Dr. F.—(*Amer. Med. and Phil. Register, vol.* 4, *p.* 488—492.)

In relation to the curative action of mercury in the treatment of lues venerea, he remarks, "The action of mercury, though primary on the nervous system, is communicated to every fibre of the body, and produces a degree of restlessness, anxiety, and debility. When taken into the system, it manifests itself by a quickened circulation, gives the blood the disposition to show the buffy coat when drawn, renders the pulse frequent and harder, increases the respiration, excites the temperature of the body, occasions a whitish fur on the tongue, and other symptoms of general inflammatory action. Its effects upon the secretions are still more apparent, producing a preternatural flow of saliva, an increased action of the mucous vessels of the trachea, lungs, digestive organs, chylopoietic viscera, and whole intestinal canal. It excites a copious discharge of urine, and in the smallest quantity operates on the skin. In its extensive influence on the body, it produces an increased action of the absorbent vessels. These may be considered the more ordinary effects of mercury, when its action is not particularly modified by the morbid condition of the constitution." Dr. F., therefore, concludes, that from the very general stimulant operation of mercury in promoting the excretions of the whole system depends its curative action. We farther conclude from these views, that from those preparations of mercury which are best calculated to secure this general action, our most approved means of relief are to be drawn; and hence the corrosive sublimate and the blue pills are to be preferred as possessing this character. We are still farther strengthened in this view by observing the effects of climate on the venereal disease, and are enabled also better to appreciate the valuable facts furnished us by Mr. Carmichael. Accordingly, the preposterous practice of Mr. Howard, and of the older writers, who advocate profuse salivation long continued, and say that the humours ought to "*flow like a river*," will find few or no advocates in the present enlightened state of knowledge. Indeed, it seems to be well established, that where salivation is early excited by a too free use of mercury, our chances of a prompt and efficacious cure are actually lessened, and sometimes entirely cut off.

There is another circumstance connected with the action and effects of mercury on the human constitution, which, though it does not strictly come under our consideration here, may nevertheless be mentioned. I allude to a peculiarity in the influence which a mercurial salivation produces, involving a point of interest in juridical medicine as well as in practice. It seems to be well established on practical authority, that salivation, having been arrested, after an interval of weeks, nay months, may be renewed by the slightest doses of mercury. Bromfield and Howard, of the Lock Hospital, give us facts of this sort. Mead mentions a case where the interval was six months, and Hamilton, of Edinburgh, relates a case of a like nature. In his lectures on forensic medicine, Dr. Francis informs me he has recorded two instances of a similar sort in his own practice, in which a few grains of mercury renewed a salivation which had been suspended for several weeks in one case, and in the other for more than four months. The inference to be deduced from occurrences of this nature renders it necessary for us always to institute the inquiry, whether the patient about to submit to mercury for the cure of venereal disorder has or has not been previously under the operation of salivation, lest ptyalism unexpectedly occur, and thus protract or defeat our curative indications. The action of mercury, to prove satisfactory in syphilis, ought to be directed on a constitution properly prepared for the purpose; the powers of the system often require to be renovated by tonics before we commence with this active agent. Hence we shall find that bark or other tonics will often be indicated before commencing with minerals in constitutions impaired by intemperance and other causes. Dr. F. informs me, that in some instances he has given as a suitable preparative charcoal or quinine, especially in cases of long-protracted syphilis, where mercury had been previously mal-administered.

The muriate of gold has not been attended with that success in the treatment of syphilis in this country, which might have been expected from the reports of its efficacy abroad. In my own practice in Baltimore, and in this city, it has proved inefficient; and, in those cases where scrofula was combined with lues, I was compelled wholly to abandon the gold, and administer the corrosive sublimate occasionally conjoined with cicuta. The learned Dr. Mitchill, however, affirms of the practice of the New-York Hospital, in which institution he introduced the method of Chrestein in 1811, that that article was capable of effecting salutary results. "Without presuming to affirm," says he, in his letter to Dr. Dyckman (*Edin. Dispensatory, Amer. ed. of* 1818), "that it is capable of eradicating the distemper in every instance, my opinion upon the whole is, that the muriate of gold will effect all that is achieved by muriate of quicksilver." Still more recently, Neil has endeavoured to substantiate the claims of auriferous preparations as adequate to the cure of venereal diseases; and this author of 1823 is almost as enthusiastic in his praises of gold as an anti-venereal remedy, as was Salmon of 1699, when he pronounced it capable of radically driving all noxious humours and matters out of the human body, elephantiasis and the French pox, because it purified the blood, and *strengthened the marrow of the bones*. I feel assured, however, if the testimony of American physicians and surgeons was impartially examined into, that their decision would coincide with that of the Academy of Paris, who, with the venerable Percy at their head, have reported unfavourably on the subject, and declared the remedial powers of this favourite remedy with some to be exaggerated and equivocal.—(See farther *American Med. Rev. vol.* 1, *article by Dr. Eberle.*) For a detail of experiments with the muriate of platina in syphilis, by Cullerier, I must refer to the *Dict. des Sciences Med. art. Platine*, 1820. I am not aware that this article has ever been used by American physicians.

Our author has made reference to the excellent paper of the late Mr. Hey, in the *Medico-Chirurg. Trans. of London, vol.* 7. That paper is a valuable contribution to our stock of knowledge on venereal diseases. Mr. Hey is one of the eminent authorities who support the opinion, that the venereal disorder is capable of affecting the fœtus in utero, nor do the discussions of Mr. John Pearson lessen our confidence in what the venerable Hey has advanced.—(See *Pearson's Life of Hey.*) That cases of this kind occasionally occur under the observation of the medical practitioners cannot be denied; I have repeatedly seen the disease thus imparted. Mahon seems to have given no proofs sufficient on this head; several cases of this nature are also furnished us by Professor Hosack in his *Medical Essays, vol.* 2; and I might also set forth in some detail those given by Professor Francis in his revised edition of Dr. Denman's Midwifery. "I have had under my own care," says Dr. F., "six cases of the venereal disease communicated to the fœtus in utero; two of these cases occurred where the genital system appeared in a perfectly sound state; in another there were ulcers of the labiæ, and constitutional disease. In two the disease was apparent immediately after birth, and in one four months had elapsed before the disease manifested itself distinctly." Cases thus contracted are doubtless best treated by the internal use of the corrosive sublimate, and to the newly-born infant we can most conveniently give the solution. See also *Dyckman, On the Pathology of the Human Fluids*, who contends that an infected nurse by lactation may communicate lues venerea. A valuable paper embracing cases illustrative of the pro

per use of mercury in venereal complaints by Dr. Darrach has recently appeared in the *North Amer. Medical and Surgical Journal, vol.* 7.—*Reese.*]

VERTEBRÆ, DISEASE OF. The case here to be considered is a disease of the spine, sometimes originating in an ulceration of the intervertebral cartilages, sometimes in a morbid condition of the cancellous structure of the bodies of the vertebræ (*Brodie on Diseases of the Joints, p.* 259), followed by a more or less complete loss of the power of using the legs.

Formerly, the affection of the limbs was generally called a palsy, and treated as a paralytic affection; to which it is in almost every respect perfectly unlike.

In the true paralysis (says Mr. Pott), from whatever cause, the muscles of the affected limb are soft, flabby, unresisting, and incapable of being put into even a tonic state: the limb itself may be placed in almost any position or posture; if it be lifted up, and then let go, it falls down, and it is not in the power of the patient to prevent, or even to retard, its fall; the joints are perfectly and easily moveable in any direction; if the affection be of the lower limbs, neither hips, knees, nor ankles have any degree of rigidity or stiffness, but permit the limb to be turned or twisted in almost any manner.

In the present case, the muscles are indeed lessened, but they are rigid, and always at least in a tonic state, by which the knees and ankles acquire a stiffness, not very easy to overcome. By means of this stiffness, mixed with a kind of spasm, the legs of the patient are either constantly kept stretched out straight, in which case considerable force is required to bend the knees, or they are, by the action of the stronger muscles, drawn across each other in such manner as to require as much to separate them. When the leg is in a straight position, the extensor muscles act so powerfully as to require a considerable degree of force to bend the joints of the knees; and when they have been bent, the legs are immediately and strongly drawn up with the heels towards the buttocks. By the rigidity of the ankle joints, joined to the spasmodic action of the grastrocnemii muscles, the patient's toes are pointed downwards in such manner as to render it impossible for him to put his foot flat to the ground; which makes one of the decisive characteristics of the distemper.

The majority of those who labour under this disease are infants or young children: adults are by no means exempt from it; but Mr. Pott never saw it at an age beyond forty; and Mr. Baynton never met with more than three instances which approached that period of life.—(*On Diseases of the Spine, p.* 4.)

In one case, however, recited by Mr. Brodie, the patient was forty-five years old (*On Diseases of Joints, p.* 268); and I have now a patient who cannot be younger. By Pott, Baynton, and several other writers, a belief is entertained that the disease is most inclined to happen in scrofulous subjects, in which opinion I am also disposed to join. There can also be no doubt of the fact stated by Mr. Pott, that it most frequently happens in weak and delicate children.

According to Mr. Pott, if the patient be a child, the account most frequently given is, that for some time previous to the incapacity of using its limbs, it had been observed to be languid, listless, and very soon tired; that it was unwilling to move much or briskly; that it had been observed frequently to trip and stumble, although no impediment lay in its way; that when it moved hastily, or unguardedly, its legs would cross each other involuntarily, by which it was often and suddenly thrown down; that if it endeavoured to stand still and upright, unsupported by another person, its knees would totter and bend under it; that it could not, with any degree of precision or certainty, steadily direct either of its feet to any particular point, but that in attempting so to do, they would be suddenly and involuntarily brought across each other; that soon after this it complained of frequent pains and twitchings in its thighs, particularly when in bed, and of an uneasy sensation at the pit of the stomach; that when it sat on a chair or a stool, its legs were almost always found across each other, and drawn up under the seat; and that, in a little time after these particulars had been observed, it totally lost the power of walking.

The same author observes, that if the incurvation be of the neck, and to a considerable degree, by affecting several vertebræ, the child finds it inconvenient and painful to support its own head, and is always desirous of laying it on a table or pillow, or any thing to take off the weight. If the affection be of the dorsal vertebræ, it is soon attended with loss of appetite, hard dry cough, laborious respiration, quick pulse, and disposition to hectic.

Mr. Pott states that an adult, in a case where no violence has been committed or received, will tell you that his first intimation was a sense of weakness in his backbone, accompanied with what he will call a heavy, dull kind of pain, attended with such a lassitude as rendered a small degree of exercise fatiguing; that this was soon followed by an unusual sense of coldness in his thighs, not accountable for from the weather, and a palpable diminution of their sensibility; that in a little time more his limbs were frequently convulsed by involuntary twitchings, particularly troublesome in the night; that, soon after this, he not only became incapable of walking, but that his power either of retaining or discharging his urine and feces was considerably impaired, and his penis became incapable of erection.

The adult also finds all the offices of his digestive and respiratory organs much affected, and complains constantly of pain and tightness at the stomach.

The true cause of the disease is a morbid state of the spine, and of some of the parts connected with it; *which distempered state of parts will, upon careful inquiry, be always found to have preceded the deformity some length of time.* In infants, this is the sole cause, and external violence has nothing to do with it. "In the adult (says Mr. Pott), I will not assert that external mischief is always and totally out of the question; but I will venture to affirm what is equal, as far as regards the true nature of the case, which is, that although accident and violence may in some few instances be allowed to have contributed to its more immediate appearance, yet the part in which it shows itself must have been previously in a morbid state, and thereby predisposed for the production of it. I do not by this mean to say that a violent exertion cannot injure the spine, nor produce a paralytic complaint; that would be to say more than I know: but I will venture to assert, that no degree of violence whatever is capable of producing such an appearance as I am now speaking of, unless the bodies of the vertebræ were by previous distemper disposed to give way; and that no supposable dislocation, caused by mere violence done to the bones of the back, which bones were before the receipt of the injury in a sound state, can possibly be attended with the peculiar symptoms of a curved spine."

For some observations connected with this point, I refer the reader to C. Bell's Surgical Observations, vol. 1.

Mr. Brodie agrees with Mr. Pott and other writers on the fact that the actual curvature must be preceded by a disease of the parts, unaccompanied with any visible deformity, and "cannot take place until the caries has made considerable progress." In the early stage of the case, therefore, when, as Mr. Brodie justly observes, the diagnosis is of the most importance, no information can be obtained from the appearance of the spine itself, the shape of which is yet unchanged; and frequently the symptoms, which do take place early, are not unequivocal. They are, according to this writer, "a pain, and some degree of tenderness in that part of the spine where the disease has begun; a sense of constriction of the chest; an uneasy feeling at the pit of the stomach and of the whole abdomen; a dis-

turbed state of the functions of the alimentary canal and of the urinary bladder; a sense of weakness and aching, and occasional cramps of the muscles of the extremities." But, as Mr. Brodie confesses, very similar symptoms may arise from other causes, and sometimes no particular complaints are made previously to the actual discovery of the curvature.—(*On Diseases of Joints*, p. 279, 280.)

I have already mentioned Mr. Brodie's opinion deduced from dissection, that in many instances caries of the spine has its origin in an ulceration of the intervertebral cartilages, beginning in their centre, and extending to their circumference, and afterward affecting the bodies of the contiguous vertebræ; but that, in other cases, the disease has its origin in the bodies of the vertebræ themselves, which are liable to the same peculiar disease of the cancellous structure, which is noticed in the articulating extremities of other bones.—(*Brodie, on Diseases of Joints*, p. 267.) This gentleman suspects that the disease, which begins in the cancellous structure of the vertebræ, is more immediately followed by suppuration than that which commences in the intervertebral cartilages, and that the first form of the disease seldom occasions so extensive a destruction of the vertebræ as the last. "But (says Mr. Brodie) farther than this, nothing which I have hitherto observed enables me to point out any circumstances in which the symptoms of these different diseases differ."—(*P.* 276.) Respecting another statement, that when the lumbar vertebræ are alone affected, the symptoms dependent on pressure or irritation of the spinal marrow are absent, I cannot say that it accords with several cases which have fallen under my own notice; that is to say, if the affection of the lower limbs is to be received as a test of such irritation or pressure.

According to Mr. Pott, the true curvature is invariably uniform, in being from within outwards; but it varies in situation, in extent, and in degree; it affects the neck, the back, or the loins; it comprehends one vertebræ only, or two, or more; and as few or more are affected, or as these are more or less morbid, and consequently give way more or less, the curve must be different.

In these cases, as Mr. Brodie remarks, "the distortion of the spine is usually of a peculiar kind, and such as nothing can produce except the destruction of the bodies of one or more vertebræ. The spine is bent forwards, so as to form an angle posteriorly; and although the destruction of the vertebræ may be the same, it is more obvious in some parts of the spine than it is in others. For example, the spinous processes in the middle of the back being long, and projecting downwards, the elevation of one of these must occasion a greater prominence than that of one of the spinous processes of the neck, which are short, and stand directly backwards.

Curvature of the spine, in the direction forwards, may arise from other causes, as a weak condition of the muscles, or a rickety affection of the bones. In general, in such cases, the curvature occupies the whole spine, which assumes the form of a segment of a circle. At other times, however, it occupies only a portion of the spine, usually that which is formed by the superior lumbar and inferior dorsal vertebræ." But here, as Mr. Brodie has found, the curvature is always gradual, and never angular; a circumstance by which it is distinguishable from the curvature produced by caries. The cases, however, he thinks have often been confounded, and some speedy and complete cures of carious spine on record, he infers, must have been cases of an entirely different nature.—(*On Diseases of Joints*, p. 282, *&c.*; and *Earle, in Edinb. Med. Journ. Jan.* 1815.)

"Lateral curvatures of the spine are alleged generally to incline to the right side; and the fact is referred (with what correctness I know not) to the undue power which is acquired by the more general use of the right arm, and of other muscles in the performance of the voluntary actions."—(*Baynton, on Diseases of the Spine*, p. 43.) It is admitted, however, that exceptions are met with, and that the lateral curvature sometimes tends to the left, and occasionally resembles the letter S reversed. On this subject I have also another rare exception to specify, which is explained by Mr. Brodie, viz. that though lateral distortions of the spine generally arise from causes independent of caries, a slight degree of lateral curvature is in some instances produced by the bodies of the vertebræ having been destroyed on one side by caries, in a greater degree than on the other.—(*Brodie, on Joints*, p. 284.)

In general, the lower limbs alone usually feel the effect. Mr. Pott, however, has seen two cases, in one of which the arms only were affected, in the other both legs and arms. Mr. Ford showed him a lad who had lost the use of both arms and legs from a curvature. An account of two similar examples was also communicated to Mr. Pott by Mr. Parke of Liverpool.

Mr. Brodie has never known the paralysis affect the muscles of the arms, when the disease was at the lower or middle part of the spine; but he agrees with Mr. Copeland, that the symptoms are not always confined to parts below the disease, and that it is not uncommon for pains in the upper extremities to accompany the paralytic affection of the legs and thighs.—(*Brodie*, p. 285. *Copeland, Obs. on Diseased Spine*, *&c.*)

Very soon after the curvature, some patients are rendered totally and absolutely incapable, not only of walking, but of using their legs in any manner: others can make shift to move about with the help of crutches, or by grasping their thighs just above the knees with both hands. Some can sit in an armed chair without much trouble or fatigue; others cannot sit up with any help. Some retain such a degree of power of using their legs, as to be able to shift their posture when in bed; others have no such power, and are obliged to be moved upon all occasions.

I have been present at the dissection of persons who died of lumbar abscesses, and who, while they lived, never suffered the peculiar loss of the use of the lower extremities, so well described by Mr. Pott, though the vertebræ were found to be diseased. However, in other instances of such abscesses, attended with caries of the spine, the legs are deprived of their power. But whether the difference is to be explained by the consideration that, in some cases, the disease of the bone may be secondary, and the abscess itself the primary complaint, I cannot determine. At all events, suppuration is frequently only an effect, the curvature existing long before the abscess; and, in such cases, the legs are affected. Some time ago, Mr. Dunn, of Scarborough, consulted me about a case, in which the latter facts were exemplified. Mr. Brodie's opinion that suppuration takes place at an earlier period, in cases where the disease begins in the cancellous structure of the bones, has been already noticed. In having a tendency to excite suppuration, and in producing the weakness of the lower extremities, the present disease of the spine appears to be materially different from the absorption of the vertebræ, sometimes caused by the pressure of aneurisms and other tumours.—(*Hodgson on Diseases of Arteries*, *&c.* p. 80.)

Mr. Pott observes, when a child appears to be what the common people call naturally weakly, whatever complaints it may have are supposed to be caused by its weak state, and it is generally believed that time and common care will remove them; but when a curvature has made its appearance, all these marks of ill health, such as laborious respiration, hard cough, quick pulse, hectical heat and flushing, pain and tightness of the stomach, &c., are more attentively regarded and set to the account of the deformity consequent to the curve, more especially if the curvature be of the dorsal vertebræ, in which case the deformity is always greatest; but whoever will carefully attend to all the circumstances of this disorder, will be convinced that most, if not all the complaints of children labouring under this infirmity, precede the curvature; and that a morbid state of the spine, and of the parts connected with it, is the original and primary cause of both.

Among many other reasons for thinking that an effect was mistaken for a cause Mr. Pott enumerates the following:

1. "That he did not remember ever to have seen this useless state of the limbs from a mere malformation of the spine, however crooked such malformation might have made it.

2. That none of those deviations from right shape which growing girls are so liable to, however great the deformity might be, was ever attended with this effect."

With respect to the treatment of diseased spine, I think one principle laid down by Mr. Pott must receive approbation; viz. that the primary and sole cause of all the symptoms is a distempered state of the parts,

composing or in immediate connexion with the spine, tending to, and most frequently ending in, a caries of the vertebræ. Hence, says he, all the ills, whether general or local, apparent or concealed; the ill health of the patient, and in time the curvature. As the disease does not originate in the limbs, no application to them can be of any use, and the great indication must be to stop the progress of the disease in the affected part of the spine.

The first suggestion of the probability that issues might prove serviceable in this disease, appears to have been made to Mr. Pott by Dr. Cameron, of Worcester, who told him that, having remarked in Hippocrates, an account of paralysis of the lower limbs cured by an abscess in the back, he had, in a case of useless limbs, attended with a curvature of the spine, endeavoured to imitate this act of nature, by exciting a purulent discharge, and that it had proved very beneficial; which was confirmed to Mr. Pott by Mr. Jeffreys, of Worcester, who had made the experiment with the same success.

The practice which Pott recommends consists merely in procuring a large discharge of matter from the integuments on each side of the distempered bones, forming the curvature, and in maintaining such discharge until the patient shall have recovered his health and the use of his limbs. They who are little conversant with matters of this sort (says Mr. Pott) will suppose the means very inadequate to the proposed end; but they who have been experimentally acquainted with the very wonderful effects of purulent drains, made from the immediate neighbourhood of diseases, will not be so much surprised at this particular one; and will immediately see how such kind of discharge, made and continued from the distempered part, checks the farther progress of the caries, gives nature an opportunity of exerting her own powers of throwing off the diseased parts, and of producing a union of the bones (now rendered sound), and thereby establishing a cure.

Mr. Pott considers it a matter of very little importance towards the cure, by what means the discharge be procured, provided it be large, that it come from a sufficient depth, and that it be continued for a sufficient length of time. He tried setons, issues by incision, and issues by caustic, and found the last in general preferable, being least painful, most cleanly, most easily manageable, and capable of being longest continued.

The caustics, he observes, should be applied on each side of the curvature, in such a manner as to leave the portion of skin covering the spinal processes of the protruding bones entire and unhurt, and so large, that the sores, upon the separation of the eschars, may easily hold each three or four peas, in the case of the smallest curvature; but in large curves, at least as many more.

The issues which modern surgeons usually make for the relief of the symptoms arising from diseased vertebræ, are larger than such as Mr. Pott himself was in the habit of forming. They now commonly prefer making an issue on each side of the spinous processes, about three or four inches long, and half an inch broad.

The size of the issue intended to be made being determined, the place where it is to be made should be accurately marked out with ink. All the skin immediately around should then be covered with adhesive plaster, in order that it may be protected from the action of the caustic. Let the surgeon next take a piece of caustic potassa or of potassa cum calce, and wrap a little tow round one end of it, so that he may take hold of it with safety and convenience. The other end of the caustic should then be moistened a little, and rubbed very quickly on the portion of the integuments which is to be converted into an eschar. The caustic is to be rubbed in this manner, till the part turns of a dull brown colour, when the caustic should be carefully washed off with a little wet tow, and a poultice applied.

As soon as the eschars admit of being removed, a row of peas or beans, connected together with thread, should be laid on the sore, and confined there with sticking plaster. A compress, containing a piece of pasteboard or sheet lead, is then to be bound over the peas or beans with a roller. In consequence of the continued pressure, the peas or beans soon form little hollows for themselves, in which they should be regularly placed every day. When the pressure is not duly maintained, the granulations are apt to rise so high, that the peas cannot be well kept on the part. In this circumstance, the surgeon must try to repress the high surface of the sore by sprinkling on it a little savine powder and subacetate of copper, mixed together in equal proportions. When this plan is unavailing, the reapplication of the caustic becomes indispensable.

Whatever time may be requisite to restore the health as well as the use of the limbs, Mr. Pott thinks that the issues should be kept open until these objects are completely fulfilled; and even longer, especially in growing children. He owns, that nothing can be more uncertain than the time required for the cure. He has seen it perfected in two or three months; and he has known it require two years; two-thirds of which time passed, before there was any visible amendment.

After the discharge has been made some time, the patient is found to be better in all general respects, and, if of age to distinguish, will acknowledge that he feels himself to be better in health; he begins to recover his appetite, gets refreshing sleep, and has a more quiet and less hectical pulse; but the relief which he feels above all others, is from having got rid of that distressing sensation of tightness about the stomach: in a little time more, a degree of warmth and a sensibility are felt in the thighs, which they had been strangers to for some time; and generally much about the same time, the power of retaining and discharging the urine and feces begins to be in some degree exerted.

The first return of the power of motion in the limbs, says Mr. Pott, is rather disagreeable; the motions being involuntary, and of the spasmodic kind, principally in the night; and generally attended with a sense of pain in all the muscles concerned.

At this point of amendment, if it may be so called, it is no uncommon thing, especially in bad cases, for the patient to stand some time without making any farther progress: this, in adults, occasions impatience, and in parents, despair: but in the milder kind of case, the power of voluntary motion generally soon follows the involuntary.

The knees and ankles by degrees lose their stiffness, and the relaxation of the latter enables the patient to set his feet flat upon the ground, the certain mark that the power of walking will soon follow; but those joints, having lost their rigidity, become exceedingly weak, and are not for some time capable of serving the purpose of progression.

An attentive examination of the morbid appearances, and their effects in different subjects, led Mr Pott to conclude, among other things, that the disease which produces these effects on the spine and the parts in its vicinity, is what is in general called scrofula.

That ulceration or caries of the bodies of the vertebræ affected, is the common morbid change, and not enlargement.

That when the attack is made upon the dorsal vertebræ, the sternum and ribs, for want of proper support, necessarily give way, and deformity, additional to the curve, is produced.

That this kind of caries is always confined to the bodies of the vertebræ, seldom or never affecting the articular processes. Two cases were seen by Pott, in which the bodies of the vertebræ were completely detached from their processes, so as to leave the membrane of the spinal marrow perfectly bare.

That without this destruction of the bodies of the vertebræ, there can be no curvature of the kind here treated of; or, in other words, that erosion is the *sine quâ non* of this disease; that although there can be no true curve without caries, yet there is, and that not unfrequently, caries without curve.

That the caries with curvature and useless limbs is most frequently of the cervical or dorsal vertebræ, the caries without curve of the lumbal; though this is by no means constant or necessary.

That in the case of carious spine, without curvature, it most frequently happens that internal abscesses and collections of matter are formed, which matter makes its way outwards, and appears in the hip, groin, or thigh; or, being detained within the body, destroys the patient: the real and immediate cause of whose death is seldom known or even rightly guessed at, unless the dead body be examined.

That what are commonly called lumbal and psoas abscesses are not unfrequently produced in this manner, and therefore when we use these terms, we should

be understood to mean only a description of the course which such matter has pursued in its way outwards or the place where it makes its appearance externally, the terms really meaning nothing more, nor conveying any precise idea of the nature, seat, or origin of a distemper subject to great variety, and from which variety its very different symptoms and events in different subjects can alone be accounted for.

That, contrary to the general opinion, a caries of the spine is more frequently a cause than an effect of these abscesses.

That the true curvature of the spine, from within outwards, of which the paralytic or useless state of the lower limbs is a too frequent consequence, is itself but *one* effect of a distempered spine; such case being always attended with a number of complaints which arise from the same cause: the generally received opinion, therefore, that all the attending symptoms are derived from the curvature, considered abstractedly, is by no means founded in truth, and may be productive of very erroneous conduct.

That when two or more vertebræ are affected, forming a large curve, however perfect the success of the treatment may be with regard to the restoration of health and limbs, yet the curvature will and must remain, in consequence of the union of the bones with each other.

That the useless state of the limbs is by no means a consequence of the altered figure of the spine or of the disposition of the bones with regard to each other, but merely of the caries: of this truth there needs no other proof than what may be drawn from the cure of a large and extensive curvature, in which three or more vertebræ were concerned; in this the deformity always remains unaltered and unalterable, notwithstanding the patient recovers both health and limbs.

Pott contends, that a morbid state of the parts previous to deformity, caries, or curve, must be allowed. All the general complaints of persons afflicted with this disorder, he says, will, upon careful inquiry, be found to have preceded any degree of deformity, to have increased as the curve became apparent, and to have decreased as the means used for relief took place: the pain and tightness about the stomach, the indigestion, the want of appetite, the disturbed sleep, &c. &c. gradually disappear, and the marks of returning health become observable, before the limbs recover the smallest degree of their power of moving.

On the other hand, it is admitted to be as true, that when, from extent or degree or inveteracy of the caries, the issues are found to be unequal to the wished-for effect, the general complaints receive no amendment; but increase until the patient sinks under them.

If all this be true, says Mr. Pott, and it be found that the issues are capable of effecting a perfect cure, even after a caries has taken place, and that to a considerable degree, is it not reasonable to conclude that the same means, made use of in due time, might prove a preventive?

Besides the forms of disease of the spine treated of in this article, the observations of Mr. Wilson prove, that the distemper may sometimes begin within the theca vertebralis, and thence extend to the bones. He also demonstrated at the College of Surgeons, scrofulous tumours in the spinal marrow. Such diseases would create a loss of power in the parts below them, without any curvature of the spine.—(*Lectures on the Skeleton, &c. p.* 397.)

In France, the same indication is followed as that on which Mr. Pott lays stress, viz., to endeavour to arrest the disease of the spine by means applied in the vicinity of the morbid parts. But instead of employing caustic issues, the moxa is used, and sometimes repeated cupping near the affected bones; both which means were particularly recommended by Desault.

Another practice which yet has partisans, though it was strongly disapproved of by Pott, is that of supporting the spine with machinery. Perhaps the latter author may have carried his objections to this method beyond all reason, and with the exception of Dr. Harrison (see *Lond. Med. and Physical Journ. Nov.* 1820), I believe no modern practitioner now ever advises it on the supposition of there being any *dislocation;* an error which formerly prevailed. As Mr. Brodie observes, certainly no machines ought ever to be employed for the purpose of elongating the spine and correcting the deformity: but if they be used simply to take off the weight of the head, chest, and upper extremities, from the diseased part of the spine, they may sometimes be of service. The late Sir James Earle had a very favourable opinion of their utility. I believe, with Mr. Brodie, that they ought never in the first instance to supersede the constant maintenance of the horizontal position; but that they may be advantageous, when circumstances make it desirable, that the patient should begin to sit up a part of the day.—(*On Diseases of the Joint, p.* 291.)

From Mr. Pott's own account, it will be seen, that he never pretended that issues kept open in the vicinity of the disease were a sure means of relief; and a late eminent surgeon has actually referred the good which Pott thought accrued from them, to the long observance of the horizontal posture. Mr. Baynton, the gentleman to whom I allude, also mentions that M. David is the only writer who has suggested that rest would effect the cure of diseases of the spine. On this point, however, Mr. Baynton was entirely mistaken, as, about eighteen years ago, Loder wrote some remarks, particularly directed to the object of recommending quietude in the present disease, as the best means of promoting anchylosis.—(See *Med. Chir. Beobachtungen, p.* 251, 8*vo. Weimar*, 1794.)

Now, although I fully concur in the propriety of keeping the patient as quiet as possible in the recumbent position, inasmuch as motion must be hurtful to the diseased part of the spine, it does not follow, because this admission is made, that issues should be rejected, and that rest must do every thing. In one part of Mr. Baynton's reasoning, an error prevails, which I shall here notice, as it seems greatly to have influenced his opinions; and, as far as I know, it has not been remarked by the critical examiners of that gentleman's book. The mistake is in supposing that the process, by which the diseased part of the spine is to be restored and united, should be conducted exactly on the same principles as the union of bones free from disease. In fact, there is an additional indication, which is, to stop the progress of the disease, for which purpose experience proves that issues, *aided by rest*, are the means affording the best chances of success. I have attended several children myself, who, from the effect of issues, recovered the use of their lower extremities, even though they could not be kept constantly at rest. I must also give my testimony to the truth of Mr. Brodie's statement, that many patients are benefited almost immediately the issues are made, or uniformly find themselves better after each application of the caustic. —(*On Diseases of Joints, p.* 282.) In some cases, however, caustic issues fail to afford relief; and when they are of no use, rest in the horizontal posture, below ground, I believe, must soon be the patient's doom. Whether the occasional failure of issues is to be ascribed to the advanced progress which the disease has made, or to its having begun in the cancellous structure of the vertebræ, as suggested by Mr. Brodie, future observation must decide.

I have now under my care a patient, who lost the faculty of sensation in one leg, and yet retained in it the power of motion; while the other leg was deprived of motion, but not of feeling. By blistering the loins and sacrum, and giving tonics and aperient medicines, I have so far succeeded in curing the patient, that he can walk about his room, and the power of feeling, in the limb that was deprived of it, is restored. Cases of this description tend to confirm the new and interesting doctrine of the double roots of the spinal nerves.

WART. Mr. Hunter observes, that a wart appears to be an excrescence from the cutis, or a tumour formed upon it, by which means it becomes covered with a cuticle, which is either strong or hard, or thin and soft, just as the cuticle is that covers the parts from which the excrescence arises. Warts are radiated from their basis to their circumference. The surface of the radii appears to be pointed, or granulated, like the surface of healthy granulations, with the exception of being harder and rising higher. The surface on which a wart is formed seems only to be capable of producing one; for the surrounding and connecting surface does not throw out a similar substance. Thus, when a wart has once begun to grow, it rises higher and higher without becoming larger at its basis. Such excrescences seem to have within themselves the power of growing; for, as Hunter remarks, after they have risen above the surface of the skin, on which their basis cannot grow larger, they swell out into a round thick substance, which becomes rougher and rougher.

In consequence of this structure, warts are liable to be hurt by bodies rubbing against them, and from such a cause they often bleed very profusely, and are rendered sore and painful.—(*On the Venereal Disease*, *p.* 250, *edit.* 2.)

As warts are adventitious substances, and not any part of the original structure of the body, their powers of life are weak. Hence, when stimulated they generally become smaller, and at length altogether disappear or drop off.

On this principle warts may frequently be cured by the application of the tinctura ferri muriati, sulphate of copper, or a powder composed of the powders of savine leaves and the subacetate of copper, in equal proportions.

However, the employment of stronger escharotics, like the nitrate of silver or the concentrated acetic acid; the removal of such excrescences with a knife or pair of scissors; or tying their necks with a ligature; are plans frequently preferred, because the cure is sooner accomplished.

The last two methods are eligible when the wart has a narrow neck; but after the removal of the excrescence, it is still proper to touch the root with the caustic or the acetic acid; for unless the whole be completely destroyed, the wart will inevitably grow again.

Warts on the pudenda and about the anus, scarcely ever withstand the effect of the powder of savine, and subacetate of copper, though they will sometimes resist a course of mercury adequate to cure lues venerea; a consideration which led Mr. Hunter to believe them not to be syphilitic. In this opinion, I believe all the best surgeons of the present day concur.

WHITLOW. (*Panaris, Onychia, Pararitium, Paronychia.*) A whitlow is an inflammation at the end of one of the fingers or thumb, exceedingly painful, and very much disposed to suppurate. The toes are also sometimes the seat of the disease.

Writers usually divide whitlows into four kinds. In the first or mildest, a vesicle filled with matter commonly arises near the root or side of the nail, after a superficial inflammation of trivial extent. The matter is situated immediately under the cuticle. Sometimes the abscess takes place under the nail, in which case the pain is severe, and not unfrequently shoots upwards as far as the external condyle.

The second kind of whitlow is chiefly situated in the cellular substance under the cutis, and for the most part occurs at the very end of the finger. In this case the inflammatory symptoms, especially the pain, are far more violent than in other common inflammations of not greater extent. However, although the pain is thus severe, it does not in general extend far from the part affected. Writers usually impute the violence of the pain, and the considerable degree of inflammation attending the complaint, to the hard and unyielding nature of the skin on the finger. To the same cause they also ascribe the difficulty of perceiving any fluctuation, after matter is formed; and the slowness with which the pus makes its way outwards.

The third kind of whitlow is distinguishable from the others by the following circumstances. With the most excruciating pain, there is little swelling in the affected finger, but a vast deal in the hand, particularly about the wrist, and over the whole forearm. The pain extends to the hand, wrist, elbow, and even the shoulder. When suppuration takes place, a fluctuation can never be felt in the finger, though it may often be distinctly perceived in the hand, at the wrist, or even somewhere in the forearm. The case is frequently accompanied with considerable fever. The disease is seated in the tendons and their sheaths, and the power of moving the fingers, and even the whole hand, is lost.

Authors describe the fourth kind of whitlow, as arising principally from an inflammation of the periosteum. The case is attended with one peculiarity, which is, that however violent the pain may be, it never extends to the hand and forearm, nor is there any external swelling of the affected finger. Suppuration generally follows very soon, the usual consequence of which is a caries, or rather a necrosis of the subjacent finger-bones.

Whitlows commonly begin on the inside of the fingers; but they do occasionally commence on the back of these parts, and even on that of the hand. Though pain about the wrist is usually the effect of inflammation in the finger, Acrel mentions a case in which the disorder was altogether confined to the hand itself.—(*Vorfälle*, *b.* 2, *p.* 191.)

Mr. Wardrop has favoured the public with an account of a particular species of whitlow, which, from its malignant character, he has denominated the *onychia maligna*. "The commencement of this disease is marked by a degree of swelling, of a deep red colour, in the soft parts at the root of the nail. An oozing of a thin ichor afterward takes place at the cleft formed between the root of the nail and soft parts, and at last the soft parts begin to ulcerate. The ulcer appears on the circular edge of the soft parts at the root of the nail: it is accompanied with a good deal of swelling, and the skin, particularly that which is adjacent to the ulcer, has a deep purple colour. The appearance of the ulcer is very unhealthy, the edges being thin and acute, and its surface covered with a dull yellow or brown-coloured lymph, and attended with an ichorous and very fetid discharge. The growth of the nail is interrupted, it loses its natural colour, and at some places appears to have but little connexion with the soft parts. In this state (says Mr. Wardrop) I have seen the disease continue for several years, so that the toe or finger became a deformed bulbous mass. The pain is sometimes very acute; but the disease is more

commonly indolent, and accompanied with little uneasiness. This disease affects both the toes and the fingers. I have only observed it on the great toe, and more frequently on the thumb than any of the fingers. It occurs, too, chiefly in young people; but I have also seen adults affected with it."—(*Wardrop, in Med. Chir. Trans. vol. 5, p.* 135, 136.)

The causes of whitlows are generally of a local nature. Writers enumerate the following as the most common: a contusion; suddenly warming the finger when it is exceedingly cold; pricks with needles or other sharp instruments; and the insinuation of irritating matter into scratches on the finger. A surgeon, in operating for a fistula in ano, has been known to cut his finger, and have, in consequence of the accident, a very severe and dangerous kind of whitlow. Richter also mentions a person, who had a most obstinate whitlow, in consequence of a slight wound on the finger, in examining the head of a horse that had the glanders. Sometimes the cause of a whitlow depends on a splinter or thorn which continues lodged in the part. Very often no particular cause whatever can be assigned for the complaint.

The first case, which occurs about the root of the nail, ought to be opened as soon as possible. When this plan is not adopted, the matter is apt to penetrate more deeply, reach the root of the nail, and occasion a loss of this part. When an effectual opening is not made, the matter collects again. In general, a detachment of the cuticle takes place as far as the abscess extends. When the inflammation has been very violent, and the matter has made its way as far as the root of the nail, the nail itself is in general gradually detached, while the denuded portion of the root of the nail acts on the sore as a foreign body, and hinders it from healing. Hence, the surgeon should repeatedly cut away as much of the lower edge of the nail as he can, and insinuate a little soft lint between the margin of the nail and the sore, in order to keep the latter from being irritated by the former. In proportion as the old nail gradually separates a new one makes its appearance.

When matter lies under the nail, an opening should be made through the part as speedily as possible for the discharge of the abscess. In order to perform this operation, Richter advises the surgeon to scrape the nail with a piece of glass till it is as thin as it can well be, when it may be cut through with a bistoury.

In the second species of whitlow, suppuration may sometimes be prevented, and the inflammation be resolved by the timely employment of proper means. When the pain is violent, and acute fever prevails, it may be advisable to bleed the patient. In a few severe cases, the application of three or four leeches to the affected finger has been known to procure prompt relief.—(*Schmucker.*) Theden thinks, that applying a roller round the finger, hand, and arm, and frequently wetting the first two parts with a lotion, are the most certain means of resolving the inflammation. Platner advises the finger to be for some time immersed in water as warm as the patient can bear. Some recommend the external use of camphorated spirit, or the linimentum ammoniæ; while others advise the affected finger to be plunged in a warm solution of soap, or an alkaline lotion. When the whitlow is occasioned by a prick, particular care must be taken that no extraneous substance remain in the puncture.

When the symptoms do not abate by the fourth day, Richter recommends an opening to be made. Even when no fluctuation is discovered he approves of making a crucial incision in the seat of the pain, and he states, that although no matter may be discharged, the patient always derives infinite relief from the operation. The benefit, he says, may either be imputed to the bleeding or to the division of the hard tense skin, which compresses the subjacent inflamed parts. Sometimes the collection of matter can be plainly felt, and, in this case, there can be no hesitation about the place where the opening should be made. However, it may be proper to remark, that the opening should always be made sufficiently large. When the surgeon makes a small puncture it soon closes again, and a repetition of the operation becomes necessary. When opening the abscess is delayed, the theca of the flexor tendons easily becomes affected, or the matter may spread to a considerable extent under the skin. Sometimes it makes its way through the cutis by ulceration, and raises up the cuticle. In this case, as soon as the cuticle has been opened, a director should be introduced into the aperture in the skin, and the latter opening be enlarged with a bistoury.

The third species of whitlow seldom affects the last phalanx of the fingers; but generally the second or third. In this case, Richter enjoins us never to defer making an opening longer than the third day. If we wait till suppuration happens, we shall wait till the tendons are destroyed and the use of the finger is lost. In the case under consideration, the matter is always of bad quality and very small in quantity. A fluctuation in the finger can seldom be felt. However, in a few instances, the matter is perceptible at the extremity of the finger or about the finger-joints; but more often in the palm of the hand, or near the wrist. In these circumstances the tendons are in general already destroyed, and a stiffness of the finger and hand is to be apprehended. When the complaint is the consequence of a puncture, the best plan, according to Richter, is at once to enlarge the wound; for, in this sort of case, all other methods are unavailing. It is not enough, however, to cut through the skin; the tendinous theca itself must be laid open.

When a collection of matter forms towards the wrist, attended with violent pain in that situation, an opening must also be made there. If an opening should have already been made in the hand, a probe may be introduced into the wound, and another aperture made in an eligible situation by cutting on the end of the instrument. In the same way Richter advises an opening to be made in any part of the forearm, where great pain, or the symptoms of suppuration may indicate its propriety.

In the fourth kind of whitlow, early incisions made down to the bone are the most certain means of obviating the danger. When such incisions are not made early enough, suppuration takes place, and the bone perishes. The cut is to be made in the place where the pain is most severe. When the first phalanx is affected, the incision may be made in front of the finger, but when the second or third is the seat of the complaint, the opening should be made on one side. However, in order that the opening may be useful, it is absolutely necessary to make it down to the bone. When the incision is delayed too long, a small quantity of unhealthy matter is usually detected, and the bone is found in the state of necrosis. As an exfoliation can hardly be expected in this situation, it is best to remove at once the diseased piece of bone. When the last phalanx alone is affected, the finger retains its form, with the exception of its end being a little shorter and flatter. When the disease, however, is situated in the third phalanx, Richter thinks it better to amputate the finger than remove the diseased bone, as the finger, if left, would always remain stiff and unserviceable.—(See *Anfangsgr. der Wundarzneykunst, vol.* 7.)

With regard to the treatment of the species of whitlow named by Mr. Wardrop *onychia maligna*, all local applications have in many instances proved quite ineffectual, and the part been amputated. The only local treatment which Mr. Wardrop has ever seen relieve this complaint has been the evulsion of the nail, and afterward the occasional application of escharotics to the ulcerated surface. I have myself seen a similar plan occasionally succeed, and the applications which appeared to answer best were arsenical lotions, Plunket's caustic, or a very strong solution of the nitrate of silver. Nothing, however, will avail, till the nail is removed, and its total separation sometimes takes up a good deal of time, unless the patient submit to the great pain of having it cut away.

In four cases of the onychia maligna, Mr. Wardrop tried with success the exhibition of mercury. It was given in small doses at first, and afterward increased, so as to affect the gums in about twelve or fourteen days. When the system was in this state, the sores in general soon assumed a healing appearance, and the bulbous swelling gradually disappeared.—(See *Med Chir. Trans. vol. 5, p.* 138.)

[Dr. J. B. Whitridge, of Charleston, S. C., informs me, that in cases of whitlow, when by neglect or mal treatment the bone becomes carious, he has frequently preserved the member by a timely removal of the diseased bone. Persons much in the habit of using the pen, and others whose livelihood depends on their re

taining the use of the thumb and fore-finger, are the subjects to whom this operation is sometimes signally beneficial. Dr. W. has several times removed the bone of the first phalanx, and twice that of the second, and still preserved sufficient flexibility of the member to use it with tolerable dexterity. The other fingers, under similar circumstances, may be amputated without materially interfering with ordinary manipulations.

This disease is so often neglected or mismanaged by timid practitioners, that in the cases alluded to, it is often important to be possessed of a remedial means at once so professional and so humane.—*Reese.*]

WOUNDS. A great deal of the subject of wounds has been already considered in the articles *Gun-shot Wounds; Head, Injuries of; Hemorrhage; Hydrophobia; Parotid Duct; Sutures; Tetanus; Throat; &c.*

A wound may be defined to be a recent solution of continuity in the soft parts, suddenly occasioned by external causes, and generally attended at first with hemorrhage.

Wounds in general are subject to considerable variety in their nature, degree of danger, facility of cure, and the consequences which are to be apprehended from them. Some wounds are quite trivial, not extending more deeply than the skin and cellular membrane; while others are very serious and dangerous, penetrating the muscles, tendons, large blood-vessels, and nerves of importance. There are also certain wounds which are not confined to the soft parts, but injure even the bones; such are many sabre-cuts, which frequently separate at once both a portion of the scalp and the subjacent part of the skull. Many wounds of the head, chest, and abdomen injure the organs contained in those cavities. In short, the varieties and the degree of danger attending wounds in general, depend very much upon some of the following circumstances: the extent of the injury; the kind of instrument with which it has been inflicted; the violence which the fibres of the part have suffered, in addition to their division; the size and importance of the blood-vessels and nerves which happen to be injured; the nature of the wounded part, in respect to its general power of healing favourably or not; whether the operations of the system at large, and life itself, can be well supported or not, while the functions of the wounded part are disturbed, interrupted, or suspended by the accident; the youth or old age of the patient; the goodness or badness of his constitution; and the opportunities which there may be of administering proper surgical aid and assistance of every kind.

All wounds of considerable size or depth, not producing immediate death, are followed by more or less disturbance of the whole constitution; by a fever, which, on account of its being an effect of the local injury, is sometimes called *symptomatic*; and sometimes *sympathetic*, in consequence of its being, as it were, the sympathy of the whole animal economy with the wounded part. It is likewise frequently named *inflammatory* fever, as being a constant attendant on severe inflammation. A description of it will be found in another part of this work.—(See *Fevers.*)

Wounds, especially those of the fingers and toes, and other tendinous parts, are occasionally productive of another form of constitutional disturbance, affecting in a violent degree the muscular system, and well known by the name of *locked-jaw*. Of this I have fully treated in another article.—(See *Tetanus.*)

Profusely suppurating wounds, the cure of which is retarded by any incidental circumstances, invariably bring on great debility, and a particular disturbance of the sanguiferous, secreting, digestive, nervous, and other systems, known by the name of *hectic* fever, of which I have also delivered an account.—(See *Fevers.*)

Another complication of wounds, often met with in crowded military hospitals, is a peculiar species of mortification, frequently supposed to be contagious; and already described in the article *Hospital Gangrene.*

Besides these consequences of wounds, it is my duty to mention another very common one, which seems to be intimately connected with the patient's temperament or habit of body. I here allude to *erysipelas*, which may be excited by a wound, instead of healthy phlegmonous inflammation.—(See *Erysipelas.*)

I may as well here also briefly advert to another complication of wounds; namely, to the formation of abscesses in the liver, lungs, around the joints, or in other important organs, situated at a considerable distance from the wounded part. These occasional suppurations in the liver and lungs, after injuries of the head, have been known to surgeons for the last sixty or seventy years. They have been noticed by Le Dran, Schmucker, and Klein; and they have again been recently brought under consideration by Mr. Rose and Mr. Arnott.—(See *Med. Chir. Trans. vols.* 14 *and* 15.) The latter writer conjectures, that they may depend upon the absorption of some specific matter from the wounded part, and, as I have elsewhere detailed (see *Veins*), he imputes the fatal symptoms of phlebitis, in which similar abscesses are frequently found in the viscera, or around the joints to the same cause, and not to the extension of the inflammation along the lining of the vein to the venæ cavæ, and even the heart.

Wounds are distinguished by surgical writers into several kinds; viz. *incised, punctured, contused, lacerated, poisoned*, and *gun-shot wounds*. They also make another equally important division into *Wounds of the Head, Thorax, Abdomen, &c.*

Of gun-shot wounds, and wounds of the head, an account has already been given.—(See *Gun-shot Wounds*, and *Head, Injuries of.*) The other cases I shall now proceed to consider.

Incised Wounds.—As a general observation, it may be stated that, *cæteris paribus*, a wound which is made with a sharp cutting instrument, which is, in short, a mere incision, is attended with less hazard of dangerous consequences than any other kind of wound whatever. The fibres have only been simply divided; they have suffered no contusion nor laceration; consequently, they are less likely to inflame severely, or to suppurate, or slough; and they commonly admit of being united again in a very expeditious manner.

Generally, simple incised wounds bleed more freely than contused and lacerated ones, which at first sometimes scarcely pour out any blood at all, although considerable blood-vessels may be injured. But this circumstance, apparently diminishing the danger of contused and lacerated wounds, is deceitful, and serves rather to render the case in reality more perilous, by inducing the inexperienced practitioner to be off his guard against hemorrhage. Thus, in gun-shot wounds, it often happens, that on their first occurrence the bleeding is trivial; but the side of some large artery having suffered great violence at the time of the accident, it may ulcerate or slough, a week or ten days afterward, and an alarming, and even fatal, effusion of blood be the result.

In cases of simple incised wounds, the bleeding, which at once takes place from all the divided vessels, is a source of very useful information to the surgeon, inasmuch as it enables him to judge what danger is to be apprehended from the hemorrhage, whether the cut vessels are large enough to demand the ligature, or, on the contrary, whether they are such as will cease to bleed either by slight pressure or of their own accord.

In a recent simple incised wound, there are three objects which the surgeon should endeavour to accomplish without the least delay. The first, and that which requires his immediate interference, is the bleeding, which must be checked. The second is the removal of all extraneous matter from the surface of the wound. The third is the reunion of the opposite sides of the injury.

When the divided vessels are not above a certain size, the bleeding soon spontaneously ceases, and no surgical measures need be taken on this particular account. When the wounded vessels are even somewhat larger, and their situation is favourable for compression with a bandage, it is often advisable to close the wound and apply compresses and a roller, rather than have recourse to ligatures, which always create a certain degree of irritation and suppuration. However, though I have made this observation, I should be exceedingly sorry to appear at all against the general preference to ligatures, whenever the wounded arteries are above a certain magnitude. In this circumstance, tying the bleeding vessels is the only safe mode of proceeding. When the artery is of considerable size, and its mouth can be readily seen, the most proper instrument for taking hold of it is a pair of forceps. In applying the ligature, the surgeon must take care to pull its ends in such a manner that the noose will not rise above the mouth of the vessel, and for the purpose of altering the direction of the force employed in tighten-

ing the ligature, the ends of the thumbs are generally made use of. The tenaculum is commonly employed for taking up arteries, which are not large and distinct.

Fine ligatures, of sufficient strength, are at present often applied, as well to large as small vessels; an improvement, to the establishment of which the experiments of Dr. Jones, and the writings of Dr. Veitch, materially contributed. One half of each ligature should always be cut off before the wound is closed, and there are some surgeons who prefer the method of cutting off all the ligature, except what forms the noose immediately round the artery.—(*Delpech, Mém. sur la Pourriture d' Hôpital, p.* 29; *Lawrence, in Med. Chir. Trans. vol.* 6, *p.* 156.) To the latter plan, however, a few surgeons have adduced objections, particularly Mr. Guthrie, who only admits the utility of it in cases where the wound will not unite by the first intention (*On Gunshot Wounds, p.* 94), and Mr. Cross, of Norwich.—(See *the London Medical Repository, vol.* 7, *p.* 353.) The experiments of Mr. Cross tend to the following conclusions:

First, If the wounds do not unite by the first intention, the ligatures may escape with the discharge, without any inconvenience.

Secondly, If common ligatures of twine are cut short, the wound may unite over them, and they may be found in abscesses after an interval of many weeks.

Thirdly, If the finest dentist's silk be employed in the same way, and the wound unite over it, the ligature may be detached from the vessel, and remain buried in an abscess, where it will be found at different periods, from one to seven months; and this may happen, whether the vessel be firmly compressed with a single ligature or divided between two ligatures, so as to imitate the circumstances under which vessels are tied after operations.

Fourthly, If Indian silk, fine as hair, be put round a vessel, so as to diminish its diameter, or to effect its obliteration by just compressing its sides together, it may remain in this situation, without exciting abscess, or producing any inconvenience. The ligature may be thus applied to compress an artery for the cure of aneurism; but not to secure vessels divided in operations. If a thin ligature be drawn sufficiently tight upon a vessel on the face of a stump to be secure, Mr. Cross is persuaded, that the extremity of the vessel which becomes insulated, as it were, must die.—(See *London Med. Reposit. vol.* 7, *p.* 363.) It deserves attention that the preceding inferences are chiefly founded on experiments made upon asses and dogs. For farther observations, see *Aneurism*, *Hemorrhage*, *Ligature*, *Surgery*, *&c.*

The bleeding having been suppressed, the next object is to remove any extraneous matter, such as dirt, bits of glass, clots of blood, &c., from the surface of the wound. Were this circumstance neglected, the plan of uniting the opposite sides of the cut by the adhesive inflammation, or by what is more frequently termed, union by the first intention, would in general be frustrated.

As soon as attention has been paid to the foregoing indications, the surgeon must put the lips of the wound in contact, and take measures for keeping them in this state until they have grown firmly together. The sides of incised wounds are kept in a state of apposition by means of adhesive plaster, a proper position, the pressure of a roller, and, in a few particular instances, by the employment of sutures.

With respect to sutures, as they create pain, irritation, and some degree of suppuration, they ought never to be employed when the parts can be kept in contact without them. However, certain cases require them, and it is admitted by many experienced surgeons that in sabre-wounds of the ears, eyelids, nose, and lips, it is proper to use them.—(See *Assalini's Manuale di Chir. Parte Seconda, p.* 10.) An account of the several kinds of sutures, with remarks on their employment, will be found in the article *Sutures*.

The best and most common method of keeping the surfaces of divided parts in contact is by means of strips of adhesive plaster. When they are to be applied, the surgeon should put the wounded limb or parts in the position which is most favourable to bringing the lips of the wound together. With this view, a position should generally be chosen which relaxes the skin and subjacent muscles. An assistant should then place the edges of the wound as evenly together as possible, and hold them in this state until the surgeon has secured them in this condition by strips of adhesive plaster, applied across the line of the wound. In general, it is deemed advisable to leave a small interspace of about a quarter of an inch between each two strips of plaster, by which means the matter cannot be confined in case of suppuration. Over these first strips, lint is to be applied, and kept in its place with other pieces of adhesive plaster. Then, if necessary, a pledget and compresses are to be put on the part, and, lastly, the bandage or roller is to be applied.

In this manner the fresh-cut surfaces are brought into contact; and to preserve them quietly in this state, is the next great aim which the surgeon should have in view. The wounded part should be laid in the posture which was found the most favourable for approximating the sides of the cut at the time of applying the dressings, and the patient should be directed to keep the part in a perfectly quiet state.

When attention is paid to these circumstances, it often happens, that the two opposite surfaces of the wound grow together again in the course of forty-eight hours, without any degree of suppuration. The process by which this desirable event is accomplished is well known among surgeons by the name of *union by the first intention*. Besides the advantage of the cure being effected in this way with the greatest expedition possible, there is still another thing much in favour of constantly promoting this method of healing wounds, which is, that the scar is much less than after any other mode of cicatrization, and the part is covered with original skin, which is always much stronger than any which can be formed as a substitute for it.

It is wonderful with what celerity union by the first intention takes place under favourable circumstances. In the course of three days, the large wound, made in the operation of amputation, is frequently all healed, except just where the ligatures are situated.

When the two sides of the wound have been brought together, before the oozing of blood has entirely ceased, Mr. Hunter conceives, that blood itself becomes the first bond of union; but, on this point, Professor Thomson of Edinburgh, entertains a doubt; and all practical surgeons agree, that the lodgement of blood on the surface of a wound is more likely to prevent, than promote, the union of the parts. In all common instances, what Mr. Hunter calls the adhesive inflammation takes place. In this process, coagulating lymph either issues from the half-closed mouths of the vessels, or from the surface of the opened cells of the cellular substance. This becomes the first uniting medium, and very soon afterward, in some inexplicable manner, a vascular intercourse is established between the opposite sides of the wound.

The power which parts of the animal body have of thus growing together, is strikingly evinced by the possibility of removing a part of one body and then uniting it to some part of another. In this latter case, there can be no assistance given to the union on one side, since the detached part, as Mr. Hunter observes, can hardly do more than just preserve its own living principle and accept of union. In this way, says the same writer, the spurs of the young cock can be made to grow on its comb, or on that of another cock; and its testicles, after having been removed, may be made to unite to the inside of any cavity of an animal.

Every one initiated in surgery has heard of the feats of Taliacotius, Garengeot, and others, who are said to have succeeded in effecting the union of parts, which were completely severed from the body. Several other not less extraordinary performances by modern surgeons are recorded.—(See *Obs. on Adhesion, with two Cases demonstrative of the Power of Nature to reunite Parts which have been by accident totally separated from the animal System, by Wm. Balfour*, 8vo. *Edinb.* 1814.) Indeed, the well-known practice of transplanting the teeth, the experiments of Duhamel and Hunter, and the number and respectable character of the testimonies upon this subject, fully convince me of the *occasional* success which may attend the endeavour to bring about such a union. Experience also fully proves the *frequent* success of an endeavour to unite a part, which retains only the slight connexion of a small piece of flesh, or even a few fibres. My friend, Mr. Lawrence, attended a case which illustrates the truth of this statement. A man on the top of a stage coach was carried under a gateway which did not leave

sufficient room for him to pass without injury, and his head was so much wounded that one of his ears was entirely separated, with the exception of an attachment by a trivial piece of integuments. Mr. Lawrence assented to the man's wish of not having the separation completed, and fixed the part in its situation with a few sutures. The consequence was, that the ear soon united again, and the patient escaped all disfigurement. Of the knowledge of the disposition of living cut surfaces to grow together with considerable expedition, surgeons, both of ancient and modern times, have availed themselves, not only in the treatment of accidental wounds, but also in the removal of deformity, as exemplified in the cure of fissures in the palate or lips (see *Hare-lip*), but most particularly in the curious and interesting art of forming new underlips and noses, and closing large deficiences in the urethra with flaps of flesh, raised from the adjacent parts, shaped according to circumstances, and laid directly down upon a fresh cut surface purposely prepared, where it is steadily confined for a certain time with sutures, or simple adhesive plaster, and pressure, as the nature of the case may indicate. Nay, sometimes, the flesh for the formation of the organ to be restored has even been taken from a distant part, as, for instance, from the arm for the restoration of parts of the face. When this was done, the limb was confined in close contact with the raw surface formed on the face, until a union between them had been effected; a division was now performed with the scalpel, and the opportunity taken to shape the portion of the limb, which was to be left behind, according as the part to be restored might be the ear, nose, or lip. At the present day, the flesh is usually taken from the adjacent parts; a connexion of the flap with the rest of the body is retained, so as to ensure some circulation of blood in it, and it is turned into any position which the circumstances may demand.—(See *Gaspar Taliacotius, Chirurgia Nova de Narium, Aurium, Labiorumque Defectu, per institionem cutis ex humero sarciendo, &c.* 8vo. *Francof.* 1598. *J. C. Carpue, an Account of two successful Operations for restoring a lost Nose from the Integuments of the Forehead,* 4to. *Lond.* 1816. *Giuseppe Baronio, Degli Innesti Animali,* 8vo. *Milan. C. F. Graefe, De Rhinoplastice, sive Arte curtum Nasum ad Vivum restituendi, commentatio, quâ prisca illius ratio iterum experimentis illustratur novisque methodis ad maorem perfectionem perduciter,* 4to. *Berol.* 1818. *Sir A. Cooper on Unnatural Apertures in the Urethra; Surgical Essays, part* 2. *H. Earle on the Re-establishment of a Canal in the place of a portion of the Urethra, in Phil. Trans. for* 1821. *A Case of restored Nose, by A. C. Hutchison. A Case of artificial Anus cured by G. F. Collier, in Med. and Physical Journ. for June,* 1820. *Delpech, Chir. Clin. t.* 2, *Paris,* 1828.)

Mr. John Bell describes the process of adhesion to be this: either the arteries of the opposite surfaces inosculate mouth to mouth, or rather each cut surface throws out a gluten; the gluten fills up the intermediate space; into that gluten the lesser arteries of each cut surface extend themselves; and it is thus, perhaps, by the generation of a new intermediate substance, that the continuity and entireness of the part are so quickly restored. If any one point fail to adhere, there the wound must run into suppuration; because, says Mr. J. Bell, at that point there is a separation of parts, which is equivalent to a loss of substance.

The same writer observes, that there are, no doubt, accidents both of the constitution and the wound which will prevent adhesion. If the patient be of a bad habit of body; if he be lying in a foul hospital, in the midst of putrid sores, and breathing a contagious air: if he be ill of a fever, or flux, or any general disease; then the properties of the body being less perfect, the wound will not adhere. Mr. J. Bell also notices, that if the wound be foul, made with a poisoned weapon, or left with foreign bodies lodged in it; or if a considerable quantity of blood be poured out into the cavity of the wound, or if there be a wounded lymphatic, or a wounded salivary duct, a wounded intestine, or a bleeding artery or vein, the immediate adhesion of the whole of the wound may be prevented. However, I cannot help remarking, that though Mr. John Bell, in imitation of most surgical writers, sets down the wound of a lymphatic as preventive of the union of wounds, I cannot say that I ever saw such an effect imputable to the cause just mentioned. Also, when an artery or vein is cut and requires to be tied, the adhesion of the wound would be prevented only just where the ligature lies, and at no other point.

There is no wound, observes Mr. John Bell, in which we may not try with perfect safety to procure this adhesion: for nothing can agree better with one surface of the wound than the opposite one, which has been just separated from it. They may immediately adhere together, and even if they should not do so, no harm is done, and the wound will yet suppurate as favourably as if it had been roughly dressed with dry caddis, or some vulnerary balsam, or acrid ointment. If one part should suppurate while one half adheres, then, says Mr. John Bell, one-half of our business is done. In short, this simple duty of immediately closing a wound is both natural and safe.—(*Discourses on the Nature and Cure of Wounds, vol.* 1.)

Upon this interesting topic of the advantages of union by the first intention, the most enlightened surgeons of all Europe now begin to entertain only one opinion. The practice is generally adopted, both in the treatment of accidental cuts and in that of wounds resulting from surgical operations. Thus Assalini, one of the best modern surgeons in Italy, begins his Manual of Surgery with the following axiom: "Wounds and injuries of the soft parts produced by cutting instruments, from the trifling wound of a vein, made for the purpose of discharging a few ounces of blood, to the incision in the uterus for the extraction of the fœtus, inclusively, should all be united by the first intention." —(See *Manuale di Chirurgia; Discorso Primo. Milano,* 1812.)

British surgeons have, indeed, been accused by M. Roux of indiscriminate partiality to the plan of uniting all incised wounds by the first intention; and his countryman Baron Larrey has wished the method to be discontinued after amputation, in order (as he says) to lessen the chance of tetanus. But the exceptions which these surgeons desire to make are few; and few as they are, they are not likely to be established, since several of the circumstances alleged as reasons for limiting so beneficial a practice are hypothetical, and far from being clearly proved.—(See *Roux, Mémoire et Obs. sur la Réunion immédiate de la Plaie, après l'Amputation circulaire des Membres,* 8vo. *Paris,* 1814. *Larrey, Mém. de Chir. Mil. t.* 4, 8vo. 1812—1817.)

Sometimes the attempt to procure union by the first intention fails, even in cases of incised wounds; but in this circumstance, no harm arises from the kind of practice that has been followed. The case, in fact, now falls into nearly the same state as would have occurred had no attempt at union been made at all. The patient has taken the chance of a quicker mode of cure; but he has not been successful, and he must now be cured by a process which, on account of its slowness, he at first wished to avoid. It is to be observed, also, that union by the first intention, if not spoiled by sutures, rarely fails so completely that there is not a partial adhesion of some points of the wound. The moment when we observe pain, inflammation, and swelling of the wound, a separation or gaping of its lips, the stitches tense (when these have been used), and the points where the stitches pass particularly inflamed, Mr. John Bell advises us to undo the bandages, draw out the sutures, and take away every thing acting like a stricture on the wound. These prudent measures, he observes, may abate the rising inflammation, and prevent the total separation of the skin, while an endeavour may still be made to keep the edges of the wound tolerably near each other by the more gentle operation of sticking plasters.

However, when the inflammation rises still higher, and it is evident that a total separation of the sides of the wound cannot be avoided, Mr. John Bell wisely recommends leaving the parts quite loose, and applying a large soft poultice; for, says he, should you in this critical juncture persist in keeping the parts together with sutures, the inflammation, in the form of erysipelas, would extend over the whole limb, attended with a fetid and bloody suppuration. After the wound has been brought into a favourable state, another attempt may be made to bring the edges near each other, not with sutures, but strips of adhesive plaster, or the gentle application of a bandage.

Mr. John Bell concludes with remarking that the suppuration, production of granulations, and all that follows, are the work of nature. The only thing that

the surgeon can usefully do is to take care of the health. When the wound does not suppurate favourably, the discharge generally becomes profuse, thin, and gleety. This state is to be amended by bark, wine, rich diet, and good air.

I shall conclude this subject of union by the first intention, with an extract from the writings of Mr. Hunter, who observes, that

"It is with a view to this principle of union, that it has been recommended to bring the sides (or lips) of wounds together; but as the natural elasticity of the parts makes them recede, it has been found necessary to employ art for that purpose. This necessity first suggested the practice of sewing wounds, and afterward gave rise to various inventions in order to answer this end, such as bandages, sticking plasters, and ligatures. Among these, the bandage commonly called the uniting bandage is preferable to all the rest, where it can be employed; but its application is very confined, from being only adapted to parts where a roller can be used. A piece of sticking plaster, which has been called the dry suture, is more general in its application than the uniting bandage, and is therefore preferable to it on many occasions.

I can hardly suppose (says Mr. Hunter) a wound in any situation where it may not be applied, excepting penetrating wounds, where we wish the inner portion of the wound to be closed equally with the outer, as in the case of hare-lip. But even in such wounds, if the parts are thick and the wound not large, the sides will seldom recede so far as to make any other means necessary. The dry suture has an advantage over stitches by bringing a larger surface of the wound together, by not inflaming the parts to which it is applied, and by neither producing in them suppuration nor ulceration, which stitches always do. When parts, therefore, can be brought together, and especially where some force is required for that purpose, from the skin not being in large quantity, the sticking plaster is certainly the best application. This happens frequently to be the case after the removal of tumours in amputation, or where the sides of the wound are only to be brought together at one end, as in the hare-lip; and I think the difference between Mr. Sharp's cross-stitch after amputation as recommended in his Critical Inquiry, and Mr. Alanson's practice, shows strongly the superiority of the sticking plaster (or dry suture). In those parts of the body where the skin recedes more than in others, this treatment becomes most necessary; and as the scalp probably recedes as little as any, it is therefore seldom necessary to apply any thing in wounds of that part; the practice will certainly answer best in superficial wounds, because the bottom is in these more within its influence.

The sticking plasters should be laid on in strips, and these should be at small distances from each other, viz. about a quarter of an inch at most, if the part requires close confinement; but when it does not, they may be at greater distances. This precaution becomes more necessary if the bleeding is not quite stopped; there should be passages left for the exit of blood, as its accumulation might prevent the union, though this does not always happen. If any extraneous body, such as a ligature, should have been left in the wound, suppuration will take place, and the matter should be allowed to vent at some of those openings or spaces between the slips of plaster. I have known a very considerable abscess formed in consequence of this precaution being neglected, by which the whole of the recently united parts have been separated.

The interrupted suture, which has generally been recommended in large wounds, is still in use, but seldom proves equal to the intention. This we may reckon to be the only one that deserves the name of suture; it was formerly used, but is now in a great measure laid aside in practice, not from the impropriety of uniting parts by this process, but from the ineffectual mode of attempting it. In what manner better methods could be contrived, I have not been able to suggest. It is to be understood that the above methods of bringing wounded parts together in order to unite them, are only to be put in practice in such cases as will admit of it; for if there was a method known, which, in all cases, would bring the wounded surfaces into contact, it would in many instances be improper, as some wounds are attended with contusion, by which the parts have been more or less dendened; in such cases, as was formerly observed, union cannot take place according to our first principle, and therefore it is improper to attempt it.

In many wounds which are not attended with contusion, when we either know or suspect that extraneous bodies have been introduced into the wound, union by the first intention should not be attempted, but they should be allowed to suppurate, in order that the extraneous matter may be expelled. Wounds which are attended with laceration, although free from contusion, cannot always be united by the first intention; because it must frequently be impossible to bring the external parts or skin so much in contact as to prevent that inflammation which is naturally produced by exposure. But even in cases of simple laceration, where the external influence is but slight, or can be prevented (as we observed in treating of the compound fracture), we find that union by the first intention often takes place; the blood which fills up the interstices of the lacerated parts, having prevented the stimulus of imperfection in them and prevented suppuration, may afterward be absorbed.

Many operations may be so performed as to admit of parts uniting by the first intention; but the practice should be adopted with great circumspection: the mode of operating with that view should in all cases be a secondary, and not a first consideration, which it has unluckily been too often among surgeons. In cases of cancer, it is a most dangerous attempt at refinement in surgery.

In the union of wounded parts by the first intention, it is hardly or never possible to bring them so close together at the exposed edges as to unite them perfectly by these means; such edges are therefore obliged to take another method of healing. If kept moist, they will inflame as deep between the cut surfaces as the blood fails in the union, and there suppurate and granulate; but if the blood be allowed to dry and form a scab between and along the cut edges, then inflammation and suppuration of those edges will be prevented, and this will complete the union, as will be described by-and-by.

As those effects of accidental injury which can be cured by the first intention call up none of the powers of the constitution to assist in the reparation, it is not the least affected or disturbed by them; the parts are united by the extravasated blood alone, which was thrown out by the injury, either from the divided vessels or in consequence of inflammation, without a single action taking place even in the part itself, except the closing or inosculation of the vessels; for the flowing of the blood is to be considered as entirely mechanical. Even in cases where a small degree of inflammation comes on, it is merely a local action, and so inconsiderable that the constitution is not affected by it; because it is an operation to which the powers belonging to the parts themselves are fully equal. The inflammation may produce a small degree of pain, but the operation of union gives no sensation of any kind whatever."—(*Hunter on the Blood, Inflammation, and Gun-shot Wounds.*)

Contused and Lacerated Wounds.—*Lacerated* wounds are those in which the fibres, instead of being divided by a cutting instrument, have been torn asunder by some violence capable of overcoming their force of adhesion. The edges of such wounds, instead of being straight and regular, are jagged or unequal.

The term *contused* is applied to wounds occasioned by some blunt instrument or surface, which has violently struck a part of the body.

These two species of wounds greatly resemble each other, and as they require nearly the same kind of treatment, writers usually treat of them together.

Lacerated and contused wounds differ from simple incised ones in appearing, at first view, much less alarming than the latter, while, in reality, they are infinitely more dangerous. In simple cut wounds, the retraction of the parts and hemorrhage are much more considerable than in a lacerated wound of the same size. However, notwithstanding these circumstances, they commonly admit of being healed with far greater ease. It is worthy of particular notice, that lacerated and contused wounds are not in general attended with any serious effusion of blood, even though large blood-vessels may be injured. I say in general, because, in the year 1813, I saw a soldier whose death was occa-

sioned by a sudden effusion of a very large quantity of blood from the internal jugular vein, which vessel had been injured by a musket-ball, that first entered the integuments behind the mastoid process, and passed obliquely downwards and forwards towards the sternum. The blood did not issue externally; but formed between the integuments and the trachea a large dark-coloured swelling, which produced almost immediate suffocation. At the memorable siege of Saragossa, Professor Assalini saw a surgeon, whose left carotid artery had been injured by a musket-ball, perish of hemorrhage in a few seconds.—(See *Assalini's Manuale di Chirurgia, p.* 32, *Milano*, 1812.)

In most cases, however, there is at first no hemorrhage of consequence from lacerated or contused wounds, and it is a circumstance that often leads inexperienced practitioners to commit great mistakes, by inducing them to promise too much in the prognosis which they make. Surgeons versed in practice, however, do not allow themselves to be deceived by the absence of hemorrhage, and in proportion as there is little bleeding, they apprehend that the violence done to the fibres and vessels has been considerable. What is it, but the contused and lacerated nature of the wound, that prevents hemorrhage from the umbilical arteries, when animals divide the navel-string with their teeth? Whole limbs have frequently been torn from the body without any hemorrhage of consequence taking place.

In the *Phil. Trans.* Cheselden has recorded a very remarkable case, in which a man's arm was suddenly torn from his body. Samuel Wood, a miller, had round his arm a rope, which got entangled with the wheel of the mill. He was lifted off the ground, and then stopped by a beam, which prevented his trunk from passing farther; at this instant the wheel, which was moving with immense force, completely tore and carried away his arm and scapula from his body. The appearance of a wound occasioned in this manner must of course be horrible, and the first idea thence arising, must naturally be that the patient cannot possibly survive. Samuel Wood, however, escaped with his life. The limb had been torn off with such velocity that he was unaware of the accident till he saw his arm moving round on the wheel. He immediately descended by a narrow ladder from the mill, and even walked some paces, with a view of seeking assistance. He now fell down from weakness. The persons who first came to his assistance, covered the wound with powdered sugar. A surgeon, who afterward arrived, observing that there was no hemorrhage, was content with bringing down the skin, which was very loose, so as to make it cover the surface of the wound. For this purpose, he used two cross-stitches. The patient was conveyed the next day to St. Thomas's Hospital, and put under the care of Mr. Fern. This practitioner employed the usual means for preventing the bad symptoms most to be expected in this sort of case. The first dressings came away without any bleeding; no alarming consequences ensued; and the patient in two months completely recovered.

When the arm was examined, it was found that the muscles inserted into the scapula were torn through near their insertions; while other muscles, arising from this bone, were carried away with it. The skin covering the scapula had remained in its natural situation, and seemed as if it had been divided precisely at the insertion of the deltoid muscle.

In La Motte's *Traité des Accouchemens* may be found an account of a little boy, who, while playing near the wheel of a mill, got his hand, forearm, and arm successively entangled in the machinery, and the limb was violently torn away at the shoulder-joint, in consequence of the lad's body not being able to pass in the direction in which the arm was drawn. The bleeding was so trivial, that it was stopped with a little lint, and the boy very soon recovered.

In the fifth vol. of the *Edinb. Med. Commentaries*, may also be perused the history of a child three years and a half old, whose arm was torn off by the wheel of a mill. Mr. Carmichael, who saw the child about an hour after the accident, found it almost in a dying state, with cold extremities, small faltering pulse, and all the right side of the body convulsed. However, there was hardly any bleeding. The arm was broken about an inch and a half above the elbow; the stump had a dreadful appearance; all the soft parts were in a contused and lacerated state, and the humerus was laid bare as high as the articulation, which was itself exposed. The skin and muscles were lacerated to a much greater extent, and in different directions. The remainder of the humerus was removed from the shoulder-joint by amputation, only as much skin and muscle being left as was sufficient to cover the wound. In two months the child was well.

In the *Mém. de l'Acad. de Chir. t.* 2, is an account of a leg being torn away at the knee-joint by a cart-wheel. The patient was a boy, about nine or ten years of age. This accident, like the foregoing ones, was accompanied with no hemorrhage. The lower portion of the os femoris, which was exposed, was amputated, together with such portion of the soft parts as was in a contused and lacerated state. The patient experienced a perfect recovery.

The preceding cases strikingly confirm the observation which I have already made, in regard to the little bleeding which usually arises from contused and lacerated wounds.

In these instances, the pain is also in an inverse ratio to the cause of the accident; it is generally very severe, when the wound is only moderately contused; and, on the other hand, when there has been so violent a degree of contusion, as at once to destroy the organization of the part, the patient suffers scarcely any pain at all.

When the bruised fibres have not been injured above a certain degree, the part suppurates; but such portions of the wound as have suffered greater violence inevitably die, and are cast off in the form of sloughs. Granulations are afterward formed, and the breach of continuity is repaired by the process of cicatrization.—(See *this word.*)

When a still greater degree of violence has been done, and especially when arteries of a certain magnitude have been injured, a mortification is too frequently the consequence. However, if the constitution be good, and the mischief not too extensive, the case may still end well. But, in other instances, the event is alarmingly dubious; for the mischief is then not limited to the wounded parts, which have suffered the greatest degree of contusion, but too frequently extends over such parts as were not at all interested by the wound itself.

The mortification arising directly from the impaired organization of parts is not what is the most alarming circumstance. A still more dangerous kind of mortification is that which is apt to originate from the violent inflammation produced by the accident. This consequence demands the utmost attention on the part of the surgeon, who must let no useful means be neglected, with the view of diminishing the inflammation before it has attained too high a degree, and very dangerous symptoms have commenced. In the first instance, he should not be afraid of letting the wound bleed a little, if it should be disposed to do so. The edges of the wound should then be gently drawn towards each other, with a few strips of sticking plaster, so as to lessen the extent of the exposed surface; but no sutures are proper. Indeed, the plan of diminishing the exposed surface of a contused wound with strips of adhesive plaster is not invariably right; because their application creates a hurtful degree of irritation. The method is chiefly advisable, when there is a large loose flap of skin, which can be conveniently brought over the wound. In other cases, it is best to leave the parts free, uncompressed, and unconfined with any adhesive plaster, because, if it were applied, its irritation would do harm, and could not possibly procure any union of the parts. Under the most favourable circumstances, hardly any part of the wound can be expected to unite by the first intention; the whole or the greater part of it will necessarily suppurate after the detachment of the sloughs. The surface will then granulate, new skin will be formed, and the part heal, just like a common wound. Perhaps, until the sloughs separate, the best application is a soft poultice, which should be put on cold, lest it bring on too great an oozing of blood.

Nothing, indeed, is so proper for checking any tendency to hemorrhage as cold applications, which are also the most effectual in preventing and diminishing the great degree of inflammation, which is one of the most dangerous consequences of this description of wounds.

No surgical writer, I think, has given more rational advice respecting contused wounds than that published by Professor Assalini. In general, says he, the treatment of contused wounds, whether they be simple and slight, or complicated and severe, requires the active employment of debilitating means in order to prevent inflammation. Cold water and ice, and general and topical bleeding, are the things usually resorted to with success. Vulnerary lotions, camphorated spirit, and other spirituous applications are improper; and if their pernicious effects are not always very evident, it is only because the contused injuries have been trifling, and in their nature perfectly easy of cure. In these cases, as well as in those of extravasations and glandular swellings, Assalini gives a preference to cold applications. The internal remedies and regimen (says he) should also be adapted to the condition of the patient. A cannon-ball, at the end of its course, may come into contact with a limb and fracture the bones, while the integuments have the appearance of being uninjured. Such cases are often attended with dreadful mischief in the soft parts around the bone, which generally sphacelate. This is an accident for which immediate amputation is mostly indispensable (see *Gun-shot wounds*); but if any thing be capable of preventing inflammation and gangrene, it is an active debilitating plan of treatment, assisted with cold applications to the injured part. In such cases, the internal and external use of stimulants is approved of by many surgeons. But Assalini prefers considering the state of the injured limb just like what it is when affected with frost; and he thinks that the employment of stimulants will necessarily produce the same effect as caloric prematurely applied to parts deadened with cold. On the contrary, from the outward employment of ice and cold lotions in these cases, and in contused injuries in general he has seen the greatest benefit derived.

Assalini conceives that reason will be found to support this practice. The operation of cold, he says, retards the course of the blood, which, meeting with only damaged vessels, augments the extravasation as it continues to flow. By lessening the temperature of the part, cold applications likewise diminish the danger of inflammation and sphacelus, at the same time that they have the good effect of rendering the suppuration which must ensue less profuse than it would be, were not the extravasation of blood and violence of the inflammation lessened by such applications, and a lowering plan of treatment.

Why, says Assalini, should not this method, which is so generally adopted to prevent the effects of concussion of the brain after blows on the head, be for analogous reasons employed in examples of extravasation and commotion in other parts of the body?—(*Manuale di Chirurgia, Parte Prima, p.* 17.) Cold applications, however, in cases of contused wounds are chiefly to be preferred for the first day or two, in order to check the increase of extravasation and inflammation. After this period, I give a decided preference to an emollient linseed poultice, which will be found the most easy dressing during those processes by which the sloughs are detached, the surface of the wound cleansed, and the origin of granulations established. When these changes have happened, the remaining sore is to be treated on the same principles as ulcers in general.—(See *Ulcer.*)

Punctured Wounds.—A *punctured* wound signifies one made with a narrow-pointed instrument, the external orifice of the injury being small and contracted, instead of being of a size proportionate to its depth. A wound produced by the thrust of a sword or bayonet affords us an example of a punctured wound.

Wounds of this decription are in general infinitely more dangerous than cuts, notwithstanding the latter have the appearance of being by far the most extensive. In cases of stabs, the greatest degree of danger always depends on the injury and rough violence which the fibres have suffered, in addition to their mere division. Many of the disagreeable consequences are also to be imputed to the considerable depth to which these wounds extend, whereby important parts and organs are frequently injured. Sometimes the treatment is rendered perplexing by the difficulty of removing extraneous substances, as, for instance, a piece of the weapon which has been left in the wound. Lastly, experience proves that punctured wounds and stabs are particularly liable to be followed by a great deal of inflammation, fever, deep-seated abscesses, sinuses, &c.

A strange notion seems to pervade the writings of many systematic authors, that all the danger and disagreeable consequences of punctured wounds depend entirely upon the narrowness of their orifices, so that suitable applications cannot be introduced to their bottom. Hence, it is absurdly recommended to dilate the opening of every stab, with the view, as is generally added, of converting the accident into a simple incised wound. Some of these writers are advocates for making the dilatation with a cutting instrument, while others, with equal absurdity, propose to enlarge the opening with tents.

Certain authors regard a punctured wound as a recent sinus, and, in order to make the inner surfaces unite, they recommend exciting a degree of inflammation in them, either by means of setons or injections.

In the earliest edition of *The First Lines of the Practice of Surgery*, I took particular pains to expose the folly and errors which prevail in most writings on this part of practice. In the above work I have remarked, that if the notion were true, that an important punctured wound, such as the stab of a bayonet, could be actually changed into a wound partaking of the mild nature of an incision, by the mere enlargement of its orifice, the corresponding practice would certainly be highly commendable, however painful. But the fact is otherwise: the rough violence done to the fibres of the body by the generality of stabs is little likely to be suddenly removed by an enlargement of the wound. Nor can the distance to which a punctured wound frequently penetrates, and the number and nature of the parts injured by it, be at all altered by such a proceeding. These, which are the grand causes of danger, and of the collections of matter that often take place in the cases under consideration, must exist, whether the mouth and canal of the wound be enlarged or not. The time when incisions are proper is, when there are foreign bodies to be removed, abscesses to be opened, or sinuses to be divided. To make painful incisions sooner than they can answer any end, is both injudicious and hurtful. They are sometimes rendered quite unnecessary, by the union of the wound throughout its whole extent without any suppuration at all.

Making a free incision in the early stage of these cases undoubtedly seems a reasonable method of preventing the formation of sinuses, by preventing the confinement of matter; and were sinuses an inevitable consequence of all punctured wounds, for which no incisions had been practised at the moment of their occurrence, it would undoubtedly be unpardonable to omit them. Fair, however, as this reason may appear, it is only superficially plausible, and a small degree of reflection soon discovers its want of real solidity. Under what circumstances do sinuses form? Do they not form only where there is some cause existing to prevent the healing of an abscess? This cause may either be the indirect way in which the abscess communicates with the external opening, so that the pus cannot readily escape; or it may be the presence of some foreign body or carious bone; or, lastly, it may be an indisposition of the inner surface of the abscess to form granulations, arising from its long duration, but removable by laying the cyst completely open to the influence of the air. Thus it becomes manifest, that the occurrence of suppuration in punctured wounds is followed by sinuses only when the surgeon neglects to procure a free issue for the matter after its accumulation, or when he neglects to remove any extraneous bodies. But as dilating the wound at first can only tend to augment the inflammation and render the suppuration more extensive, it ought never to be practised in these cases, except for the direct objects of giving free exit to matter already collected, and of being able to remove extraneous bodies palpably lodged. I shall once more repeat, that it is an erroneous idea to suppose the narrowness of punctured wounds so principal a cause of the bad symptoms with which they are often attended, that the treatment ought invariably to aim at its removal.

Recent punctured wounds have absurdly had the same plan of treatment applied to them as old and callous fistulæ. Setons and stimulating injections, which, in the latter cases, sometimes act beneficially, by exciting such inflammation as is productive of the effusion

of coagulating lymph, and of the granulating process, never prove serviceable when the indication is to moderate an inflammation which is too apt to rise to an improper height. The counter-opening that must be formed in adopting the use of a seton is also an objection. However, what good can possibly arise from a seton in these cases? Will it promote the discharge of foreign bodies, if any are present? By occupying the external openings of the wound, will it not be more likely to prevent it? In fact, will it not itself act with all the inconveniences and irritation of an extraneous substance in the wound? Is it a likely means of diminishing the immoderate pain, swelling, and extensive suppuration so often attending punctured wounds? It will undoubtedly prevent the external openings from healing too soon; but cannot this object be effected in a better way? If the surgeon observe to insinuate a piece of lint into the sinus, and pass a probe through its track once a day, the danger of its closing too soon will be removed.

The practice of enlarging punctured wounds by incisions, and of introducing setons, is often forbidden by the particular situation of these injuries.

In the first stage of a punctured wound, the indication is to guard against the attack of violent inflammation. When no considerable quantity of blood has been lost, general and topical bleeding should be practised. In short, the antiphlogistic plan is to be followed. As no man can pronounce whether such a wound will unite or not, and as no harm can result from the attempt, the orifice ought to be closed, and covered with simple dressings. In such cases, cold applications are also highly commendable. Whether gentle compression might be made to promote the adhesive inflammation or not may be doubtful: I confess that I should not have any reliance upon its usefulness. Perfect quietude is to be observed. When the pain is severe, opium is to be administered.

Sometimes, under this treatment, the surgeon is agreeably surprised to find the consequent inflammation mild, and the wound speedily united by the first intention. "Numerous are the examples of wounds, which penetrate the large cavities, being healed by the first intention, that is, without any suppuration. Even wounds of the chest itself, with injury of the lungs (continues an experienced military surgeon and professor), ought to be united by the first intention."—(*Asalini, in Manuale di Chirurgia, parte seconda, p.* 13.) More frequently, however, in cases of deep stabs the pain is intolerable; and the inflammatory symptoms run so high as to leave no hope of avoiding suppuration. In this condition, an emollient poultice is the best local application; and when the matter is formed, the treatment is like that of abscesses in general.—(See *Suppuration.*)

Poisoned Wounds: Bite of the Viper.—If we exclude from present consideration the bites of mad dogs, and other rabid animals, which subject is fully treated of in the article *Hydrophobia*, wounds of this description are not very common in this kingdom. In dissections, pricks of the hand sometimes occur, and they are, in reality, a species of poisoned wound, frequently causing considerable pain and irritation in the course of the absorbents; swelling and suppuration of the lymphatic glands of the arm or axilla; and severe fever and constitutional irritation. An instance of the fatal consequences of such an injury must still be fresh in the recollection of the profession; and some others of yet more recent date have taken place in this metropolis.—(See *London Medical Repository, vol.* 7, *p.* 288.)

In many instances, however, surgeons wound their fingers in dissecting bodies, and no particular ill consequences ensue. The healthy and robust are said to suffer less frequently after such accidents than persons whose constitutions have been weakened by hard study, excesses, pleasure, or previous disease. It is remarked, also, that pricks of the fingers, met with in opening the bodies of persons who have died of contagious diseases, and where a virus or infectious matter might be expected to exist in such bodies, do not communicate the infection. Doubtless (observes Richerand) the activity of certain animal poisons, from which the venereal and several other diseases arise, is extinguished with life.—(*Nosographie Chir. t.* 1, *p.* 102, 103, *ed.* 4.) This is a point, however, that does not seem to me by any means established; and that the small-pox can be communicated from a corpse to a person who does not even touch the body, was exemplified the spring of 1829 in the cases of two students at St. Bartholomew's, one of whom was my own nephew. The disease was caught by merely attending a lecture in the anatomical theatre, where the body of a black, who had died of confluent small-pox, was produced.

With regard to the treatment of the pricks of dissecting scalpels, the surgeons of the continent recommend the immediate cauterization of the little wounds with a grain of caustic potassa, or the liquid muriate of ammonia. Tonic remedies, particularly wine, are prescribed, and great attention paid to emptying the bowels.

[Dr. Godman, late Professor of Anatomy in Rutgers Medical College, has related a most interesting case of dissection wound, which terminated fatally in the person of Adrian A. Kissam, a student of medicine, who received a wound, about one-third of an inch in length, across the fleshy part of the last joint of his left middle finger, which bled freely. He died on the 6th day after the injury.—(See *Amer. Journal of Med. and Phys. Science, vol.* 1.)—*Reese.*]

The stings of bees, wasps, and hornets are also poisoned wounds, though they are seldom important enough to require the assistance of a surgeon. The hornet is not found in Scotland; but it is an inhabitant of several of the woods in England. Its sting, which is more painful than that of a bee or wasp, is not, however, often the occasion of any serious consequences. The stings of all these insects are attended with a sharp pain in the part, very quickly succeeded by an inflammatory swelling, which, after a short time, generally subsides of itself. When the eye is stung, as sometimes has happened, the effects may be very severe, as is elsewhere noticed.—(See *Ophthalmy.*) It has been lately observed, that the pain of the stings of venomous insects, like the bee, depends less upon the introduction of the sting into the part than upon that of the venomous fluid. The experiments of Professor Duméril tend to prove, that when the little poison-bladder, situated at the base of the sting, has been cut off, a wound with the sting then produces no pain. The poison flows from the vesicle through the sting at the instant when this passes into the flesh. The exact nature of the venomous fluid is not known. When applied to mucous surfaces, or even to the surface of the conjunctiva of the eye, it causes no disagreeable sensation; but when it is introduced into the skin by means of a needle, it immediately excites very acute pain.

Oil, honey, spirit of wine, the juice of the plantain, and a variety of other local applications, have been extolled as specifics for the relief of the stings of insects. Modern experience, however, does not sanction their claim to this character. In fact, none of these applications either neutralize the poison or appease with superior efficacy the pain of the sting.

These cases should all be treated on common antiphlogistic principles, and the most rational plan is to extract the sting, taking care, in the first instance, to cut off the little poison-vesicle with scissors, lest in the attempts to withdraw the sting, more of the virus be compressed into the part. The stung part should then be immersed for a time in ice-cold water, and afterward covered with linen wet with the liquor plumbi acetatis dilutus. Were the inflammation to exceed the usual degree, leeches and aperient medicines would be proper. In short, as there is no specific for the cure of these cases, they are to be treated with common antiphlogistic means.

With regard to the bites of serpents, those inflicted by the rattlesnake of America, and the cobra di Capello of the East Indies, are the most speedily mortal. Indeed, this is so much the case, that sometimes there is scarcely an opportunity of trying any remedies; and even when the patient is not destroyed thus rapidly, there is such general disorder of the nervous system, with repeated faintings and sickness, that medicines cannot well be retained in the stomach, at least for some time.

Mr. Catesby, in the Preface to his Natural History of Carolina, informs us, that the Indians, who, by their constant wanderings in the woods, are liable to be bit by snakes, know, as soon as they receive the injury, whether it will prove mortal or not. If it be on any part at a distance from large blood vessels, or where the circulation is not vigorous, they apply their reme-

dies; but if any vein of considerable magnitude be hurt, they quietly resign themselves to their fate, knowing that nothing can then be of service. Among the remedies on which they chiefly depend, are senega root, ammonia, and, particularly, strong doses of arsenic, as will be presently noticed again.

If we put out of consideration animals affected with rabies, the viper inflicts the worst poisoned wound ever met with in these islands. In fact, it is an animal that inserts into the part which it bites a poison capable of exciting very serious consequences. The jaws of the viper are furnished with teeth, two of which in the upper jaw are very different from the rest. These, which are about three lines long, are covered, for about two-thirds of their length, with a membranous coat or sheath, are of a curved shape, and articulated with the jaw-bone. When the animal is tranquil, and its mouth shut, they lie down with their points turned backwards; but they instantly project forwards when it is irritated and about to bite. In them are canals which terminate by a very narrow fissure, on their convex sides, a little way from their points. The rest of these fangs is very hard and solid; and the canal is usually filled with a transparent, yellowish fluid, the poison of the viper.

This venomous fluid is secreted by two glands, or rather by two clusters of glands, one on each side of the head, placed on the front of the forehead, directly behind the eyeball, under the muscle which serves to depress the upper-jaw. Thus the muscle cannot act without pressing upon them, and promoting the secretion of the fluid which they are destined to prepare. A little bag or vesicle, connected to the base of the first bone of the upper-jaw, as well as to the end of the second, covers also the roots of the curved fangs, and forms a receptacle for the venom.

The viper is chiefly found in hilly, stony, and woody districts, and seldom in flat or marshy places. It is not its nature to attack man, or large animals, except when provoked. Its venom is only employed for the destruction of smaller animals, such as mice, frogs, &c., which are usually swallowed whole, and to the digestion of which the venomous secretion is by some writers supposed to contribute. When, however, a viper is pursued, trod upon, taken hold of, or hurt, it immediately bites, and, were it only on account of the shape of the fangs, the wound might be attended with very unpleasant effects; but it is certain of being so, by reason of the species of inoculation which complicates it, and of which the mechanism is as follows:

When a viper is about to bite, it opens its mouth very wide. The two curved fangs, which had previously lain flat down in the cavity of the membrane attached to their base, now project and become perpendicular to the lower-jaw. When the bite takes place, the poison is propelled through the fangs by the contraction of the muscles and the closure of the mouth, and is injected into the wound with a force proportioned to its accidental quantity at the time, and the vigour of the animal.

The bite of a viper is quickly followed by severe effects, some of which are local and the others general; but it is with the former that the disorder invariably commences. At the instant of the bite, the bitten part is seized with an acute pain which rapidly shoots over the whole limb, and even affects the viscera and internal organs. Soon afterward, the wounded part swells and reddens. Sometimes the tumefaction is confined to the circumference of the injury; but most frequently it spreads extensively, quickly affecting every part of the limb, and even the trunk itself. A sanious fluid is often discharged from the wound, around which phlyctenæ arise similar to those of a burn. After a short time, however, the pain abates considerably; the inflammatory tension changes into a doughy or œdematous softness; the part grows cold; and the skin exhibits large livid spots like those of gangrene. The general symptoms also come on with celerity; the patient is troubled with anxiety, prostration of strength, difficulty of breathing, and cold profuse sweats. Vomiting frequently occurs, and sometimes copious bilious evacuations from the bowels. These symptoms are almost constantly attended with a universal yellowness and excruciating pain about the navel.

The effects occur in the same way in nearly all subjects, with some differences depending upon the particular irritability and constitution of the patient; the high or low temperature of the atmosphere; the greater or less anger of the viper; the number of its bites, the size of the reptile itself; the depth to which the fangs have penetrated; and whether the bitten part happens to be one of great sensibility, or was naked or not, at the time of the accident. In general, weak, pusillanimous persons, of bad constitutions and loaded stomachs, suffer more sudden and alarming ill consequences than strong, healthy subjects who view the danger without fear. Several bites are, of course, more dangerous than a single one; and, lastly, it has been remarked, that the venom of the viper is more active in summer than the spring.

A year or two ago, however, the newspapers recorded the death of a servant, from the inadvertent application of the poison to a scratch on his hand, as he was examining the fangs and venomous organs of a viper perfectly torpid in the winter season.

Severe, however, as the effects of the bite of a viper may be, they are far from being so perilous as they are commonly supposed to be. Indeed, the injury rarely proves fatal to an adult, even when inflicted by a viper in the middle of summer, the period when the animal is most active and vigorous. Exceptions to this common belief, however, are upon record. Thus, in the year 1816, a woman in France, aged sixty-four, was bit on the thigh by a viper, and died in thirty-seven hours, notwithstanding the internal use of the liquor ammoniæ, and the enlargement of the wound and cauterization of it with this fluid. In this case, it is to be observed, that an hour elapsed before any thing was done. —(See *Annales du Cercle Médicale*, *t.* 1, *p.* 44, 8*vo. Paris*, 1820.)

Fontana, therefore, was not exactly correct in concluding, that the bite of an ordinary viper will not prove fatal to a full-grown person, nor even to a large dog, though it does so to smaller animals. Five bites from three strong and healthy vipers were not able to kill a dog weighing sixty pounds; and as this dog was little more than a third part of the weight of an ordinary man, Fontana supposed that a single bite could never be fatal to an adult. He says, that he had seen a dozen cases himself, and had heard of fifty more, only two of which ended fatally. Concerning one of these cases he could get no information; the other patient perished of gangrene twenty days after the bite. The mortification began three days after the accident, the bitten place having been deeply scarified almost as soon as the injury was received. Fontana believes, that much of the faintness, &c. which ensues upon the bite of a viper, is the mere effect of terror. "Upon a person being bit (says he), the fear of its proving fatal terrifies himself and the whole family. From the persuasion of the disease being mortal, and that not a moment is to be lost, they apply violent or hurtful remedies. The fear increases the complaint. I have known a person that was imperceptibly bit in the hands or feet, and who, after seeing the blood, and observing a viper near him, suddenly fainted away; one, in particular, continued in a swoon for upwards of an hour, until he was accidentally observed and recovered out of it by being suddenly drenched in cold water. We know that death itself may be brought on by violent affections of the mind, without any internal disease. Why may not people who are bit die from a disease produced entirely by fear, and who would not otherwise have died from any complaint produced by the venom?" Although it must be owned that Fontana bestowed a great deal of attention upon this subject, the above reasoning is hypothetical and inconclusive. If it were to be granted, that some very timid, delicate, or nervous people die from fear alone, it could not be admitted, that the generality of people bit by snakes perish also from the violent effect of mental alarm.

Whenever the patient dies, the catastrophe is always ascribable to the quantity of venom inserted in the wound; the number of bites; their situation near important organs; and the neglect of proper means of relief. In ordinary cases of a single bite upon the extremities, the patients would get well even without any assistance; but the symptoms would probably be more severe and the cure slower.

From some facts recorded by Sir Everard Home, and observations made on the operation of the poisons of the black-spotted snake of St. Lucia, the cobra di

Capello, and the rattlesnake, it appears, that, "the effects of the bite of a snake vary according to the intensity of the poison. When the poison is very active, the local irritation is so sudden and so violent, and its effects on the general system are so great, that death soon takes place. When the body is afterward inspected, the only alteration of structure met with is in the parts close to the bite, where the cellular membrane is completely destroyed, and the neighbouring muscles very considerably inflamed. When the poison is less intense, the shock to the general system does not prove fatal. It brings on *a slight degree of delirium, and the pain in the part bitten is very severe;* in about half an hour, *swelling takes place from an effusion of serum in the cellular membrane*, which continues to increase, with greater or less rapidity, for about twelve hours, extending during that period into the neighbourhood of the bite. *The blood ceases to flow in the small vessels of the swollen parts; the skin over them becomes quite cold; the action of the heart is so weak that the pulse is scarcely perceptible, and the stomach is so irritable that nothing is retained by it. In about sixty hours, these symptoms go off; inflammation and suppuration take place in the injured parts;* and when the abscess formed is very great, it proves fatal. When the bite has been in *the finger*, that part *has immediately mortified.* When death has taken place under such circumstances, *the absorbent vessels and their glands have undergone no change similar to the effects of morbid poisons*, nor has any part lost its natural appearance, except those immediately connected with the abscess. In those patients who recover with difficulty from the bite, the symptoms produced by it go off more readily and more completely than those produced by a morbid poison, which has been received into the system."—(*Sir E. Home, Case of a Man who died in consequence of the Bite of a Rattlesnake, in Phil. Trans.* 1810.)

[There is scarcely to be found a more interesting case of its kind than that recorded by Sir Everard Home, as quoted by our author, and the history of Soper deserves to be studied with all the minuteness which Sir Everard has given to it. Mr. Home mentions that the intellectual powers of the patient were materially affected. This is an occasional circumstance only in cases of poisoning from venomous animals. Such appears to have been the fact in the case of a young man, Mr. A., of New-York, who was in 1812 seriously bitten in the arm by a rattlesnake, that had been kept in confinement for a public show. The action of the poison, according to Dr. Francis, began to manifest its effects as in the instance of Soper (Home's case), within the first half-hour, and its local changes, such as great swelling, pain, &c., were also similar. But in the case of A. the mind preserved its wonted functions throughout his whole illness. When the bite is inflicted in a large vein, its effects seem to be more immediate and its fatality more certain than under other circumstances.—(See *Francis on Med. Jurisprud. New-York Med. and Phys. Journal, vol.* 2.)—*Reese.*]

Numerous remedies for the bites of common vipers have obtained celebrity. According to certain writers, each of these remedies has effected wonderful cures; and yet, as Boyer well remarks, every one of them has been in its turn relinquished for another, the sole recommendation of which has frequently consisted in its novelty. Any of these boasted medicines, though of opposite qualities, cured or at least seemed to cure the patients, and the partisans of each considered he had a right to extol his own remedy as a specific, when the patient to whom he administered it was seen to recover perfectly, after suffering a train of severe symptoms. But the reason of this pretended efficacy becomes obvious, when one knows that the bite of a viper is of itself rarely mortal to the human subject, and that the severity of the symptoms materially depends upon the quantity of the venom in the wound.—(*Boyer, Traité des Maladies Chir. t.* 1, *p.* 428.)

The treatment of the bite of a viper is divided into local and general means.

The local treatment has for its principal object the destruction of the venom, the prevention of its entrance into the vessels or the removal of it from the wound.

Of scarifying the wound, I shall only say that it promises no utility, if it be practised with view of letting such dressings be applied as are extolled as specifics; for we now know that no local application is entitled to this character. Fontana was an advocate for applying a ligature round the limb, in order to check the ingress of the venom into the circulation; and he thought that he had seen much good result from this practice. Sir Everard Home is also of opinion, that "the only rational local treatment to prevent the secondary mischief, is making ligatures above the tumefied part, to compress the cellular membrane, and set bounds to the swelling, *which only spreads in the loose parts under the skin*, and scarifying freely the parts already swollen, that the effused serum may escape, and the matter be discharged as soon as it is formed. Ligatures (he says) are employed in America, but with a different view, viz. to prevent the poison being absorbed into the system."—(*Phil. Trans. for* 1810, *p.* 87.) At all events, if compression be employed, it should be so regulated as not to create any risk of gangrenous mischief by its interruption of the circulation. With respect to scarification of poisoned wounds, the investigations of Dr. Barry lead him to entertain a different view of them from that adopted by the foregoing writer, as will be presently noticed.

Suction of the wound has been proposed, and seems now to be supported both by reason and experience, as I shall presently explain in noticing the valuable researches of Dr. Barry.

One of the most certain methods of removing the virus consists in the excision of the bitten part. This operation, however, would hardly be proper, unless done immediately after the injury, before much inflammation had come on. It is likewise a practice to which many patients would not assent, and even some surgeons might deem the proceeding too severe in relation to the bite of the viper of this country. The bite might also be inconveniently situated for the excision of the parts. Excision, as Dr. Barry observes, can only be of use in proportion to its extent. If it reach beyond the poison it will certainly save, but not otherwise; and owing to the wider mouths of the vessels being now exposed to the atmospheric pressure, the particles of poison beyond the boundary of the excision, will pass with increased rapidity to the heart.—(*Barry's Researches, &c. p.* 159.)

Another plan more commonly preferred is that of destroying the envenomed part with caustic or the actual cautery. When this is done in time, it is said that the poison will be prevented from extending its irritation over the system. The caustic and cautery, it is conjectured, may also have the effect of chemically destroying the venom itself, while they tend to hinder its passage into the circulation, inasmuch as they destroy the neighbouring absorbent vessels. The caustic which Fontana preferred was potassa. But, as Boyer sensibly remarks, every caustic of equal strength must infallibly have the same effect, as its mode of operating is that of destroying the point of irritation, viz., the seat of the venom. In France, liquid caustics are preferred, the fluid muriate of antimony, the liquor ammoniæ, or the sulphuric or nitric acid, because their action is quicker, and they more certainly penetrate to the bottom of the wound.—(*Traité des Mal. Chir. t.* 1, *p.* 429.) Either of these liquids may be applied by means of a slender-pointed bit of wood, which is to be dipped in it, and then introduced into the punctures made by the fangs of the reptile. The piece of wood should be withdrawn, wet once more, and applied again. If a drop of the caustic can be inserted, so much the better. When the bite is very narrow and deep, the caustic cannot well be introduced before the mouth of the wound is somewhat enlarged with a lancet. A little bit of lint may then be wet in one of the above fluids, and be pressed deeply into the wound. The actual and potential cautery, like excision, will only succeed, when their action extends beyond the limits of the poison.

After the caustic has produced an eschar, the best application is an emollient poultice.

It is not, however, every bite of a viper that requires local treatment, even of this degree of severity. When the wound is superficial; the viper benumbed with cold; its poison considerably exhausted by its having previously bitten other animals; the swelling inconsiderable; and the patient neither affected with prostration of strength nor pain about the præcordia; a few

drops of ammonia may be introduced into the wound, and a small compress wet with the same fluid applied. Formerly, olive oil was considered, in England, one of the best applications for the bites of snakes, and its virtues were afterward extolled in France by Pouteau; but, says Boyer, it possesses no specific efficacy, as the experiments of Hunaud and Géoffroi have decidedly proved.—(*Traité des Mal. Chir. t.* 1, *p.* 431.) Suction of poisoned wounds, and especially of that occasioned by venomous snakes, is an ancient proposal, and one, the principle of which has been rendered exceedingly important by the experiments and researches of Dr. Barry. Several dogs and rabbits were bitten by vipers. To the bites of some, Dr. Barry applied the cupping-glass; to the bites of others nothing: and all the animals abandoned did not ultimately perish; yet when the cupping-glass was applied for half an hour to such as had been bitten by one, two, and sometimes three vipers, they suffered no symptom whatever of constitutional poisoning, while those which were left to nature were invariably attacked with convulsions and stupor, and the dogs with vomiting.—(See *Exp. Researches on the Influence of Atmospheric Pressure upon the Blood in the Veins, &c. p.* 121, 8*vo. Lond.* 1826.) From the experiments detailed in this work, Dr. Barry deduces the following inferences in relation to our present subject. First, That neither sound nor wounded parts of the surface of a living animal can absorb, when placed under a vacuum. Secondly, That the application of the vacuum by means of a piston cupping-glass, placed over the points of contact of the absorbing surface, and the poison, which is in the act of being absorbed, arrests or mitigates the symptoms caused by the poison.—(*Exp. No.* 4.) Thirdly, That the application of a cupping-glass for half an hour deprives the vessels of the part over which it is applied of their absorbent faculty, for an hour or two after the removal of the glass.—(*Exp. No.* 5.) Fourthly, That the pressure of the air forces into the vacuum, even through the skin, a portion of the matter introduced into the cellular tissue by injection, that is, if the skin of the animal be not too dense, as in the dog. —(*Exp. No.* 16—20. *Barry, op. cit. p.* 134.) Another important remark made by this author is, that when the soft parts about a wound, however minute, are forced into the vacuum of a cupping-glass, the point which offers the least resistance to the exit of the fluids contained in these parts is the little wound itself. But if scarifications have been made round it, this is no longer the case. "Therefore, the balance between the vacuum within the glass and the pressure without, will tend to be established by a discharge from the scarifications, and not from the original wound. Hence, the probability of the poison being forced out of the wound, and the vessels around it, will be diminished in proportion to the magnitude of the scarifications. If these scarifications extend beyond the area of the vacuum, the contents of the vessels thus divided will cease to be influenced by it, and, therefore, whatever portion of the poison may have passed beyond the point of division, will be carried to the heart just as if no vacuum had been applied."—(*Op. cit. p.* 156.) According to Dr. Barry, if actual or potential cauteries are used, and any portion of the poison remain beyond the depth to which their action may extend, the application of the vacuum will be perfectly useless, because the openings through which the poison might have been pressed out, are sealed up. He thinks that the ligature, recommended by Celsus to be placed between the wound and the heart, but not so tightly as to deprive the limb of sensation, should, with simple ablution of the part, and protecting it from the contact of air, be the only remedial measures ever suffered to precede the application of the vacuum; and even these, only when a cupping-glass or suction by the mouth cannot be immediately commanded.

It is farther remarked by Dr. Barry, that when the cupping-glass has been applied for an hour to the poisoned part previously to excision, the contents of all the vessels will have acquired a retrograde direction; and from not being permitted to flow freely into the vacuum, a perfect stagnation of the fluids is established. Hence, the loss of the absorbing faculty of the cupped surface.—(*Exp.* 5 *and* 7.) Thus, says he, by allowing the first cupping to precede the excision of the part, not only is there a greater quantity of the poison removed, but the danger of a more rapid absorption is avoided; while the certainty of extracting a still farther portion, or perhaps the whole of what may have remained, constitutes an additional and important advantage to be obtained by the second cupping. The advantage of the actual cautery, after excision and the second cupping, depends upon its hermetically closing the mouths of the small vessels, and rendering the tubes for a certain extent incompressible. Their absorbing powers are therefore suspended, because, as Dr. Barry argues, the pressure of the atmosphere can neither force any thing into them, nor compress them upon their own contents.—(See *Barry's Researches on the Influence of Atmospheric Pressure upon the Blood in the Veins, &c. p.* 157, 158.) These observations relate to poisoned wounds in general, and more especially to the treatment of hydrophobia, and of other cases where the symptoms resulting from the poison are of an exceedingly dangerous and rapid description.

With respect to the general treatment of the bite of a viper or of any other venomous snake, if we exclude emetics, of which Dr. Mead had a high opinion when the patient was much jaundiced, the favourite medicines are cordials, ammonia, and arsenic. The ancients employed theriaca, mithridates, &c., and the carbonate of ammonia. Of all stimulants, however, the liquor ammoniæ is that which now obtains the greatest confidence, or else the *eau de luce*, which only differs from the fluid ammonia in containing a small quantity of the oleum succinatum. In France, this remedy is even at the present time regarded as having the best claim to the title of a specific for the bite of a viper.—(*Boyer, op. cit.*)

In France, Bernard de Jussieu first tried ammonia in the year 1747 (see *Hist. de l'Acad. des Sciences*, 1747); since which time it has been extensively employed for the cure of the bites of vipers, both as an internal and external remedy. It had, however, been highly praised by Dr. Mead at a much earlier period.

A few drops of the remedy are to be exhibited every two hours; but as it is very powerful, it must always be diluted with tea, or some other drink, or the mistura camphoræ. The dose, however, must depend upon the age and constitution of the patient, and the intensity of the symptoms. Four or five drops suffice for a person of weak, delicate, irritable habit; but twelve or fifteen may be given to stronger subjects, when the symptoms are violent. With ammonia, some practitioners order wine.

In St. George's Hospital, the man who was bit by the rattlesnake kept for exhibition took aperient medicines, the liquor ammoniæ, ether, the spiritus ammoniæ, comp. opium, and other stimulants; but without any apparent benefit. The disease followed that course which Sir E. Home has described as usual when the shock on the system is not directly fatal, and the mischief in the arm ultimately produced the man's death.—(See *Phil. Trans.* 1810.)

From the following passage in relation to the bites of snakes in general, it seems that Sir Everard Home in 1810 had no confidence in any medicines which had then been duly tried. "The violent effects which the poison produces on the part bitten, and on the general system, and the shortness of their duration, where they do not terminate fatally (says he), have frequently induced the belief that the recovery depended on the medicines employed; and in the East Indies, eau de luce is considered as a specific.

There does not appear to be any foundation for such an opinion; for when the poison is so intense as to give a sufficient shock to the constitution, death immediately takes place; and where the poison produces a local injury of sufficient extent, the patient also dies, while all slighter cases recover. The effect of the poison on the constitution is so immediate, and the irritability of the stomach so great, that there is no opportunity of exhibiting medicines till it has fairly taken place, and then there is little chance of beneficial effects being produced."—(*Sir E. Home, in Phil. Trans.* 1810.)

Fontana also had little faith in reputed antidotes; but it is to be noticed, that his observations refer only to the bites of vipers. "In no country (says he) through which I passed, could I ever find any two people or persons bit by the viper, either in the mountains or valleys, that used the same remedies. Some used theriaca alone, either externally or internally

applied; others, common oil; a third set used stimulants, such as the strongest spirituous liquor; while others, on the contrary, tried every different kind of sedative. In short, there is hardly any active kind of medicine that has not been tried as a cure in this disease; while at the same time it is certain, that, under all the varieties of application, none of the patients died." Hence, Fontana concluded that none of the remedies had any effect in curing the disease.

Later observations, however, tend to raise our hopes, that a medicine is now known which really seems to possess considerable efficacy against the bite even of a very formidable kind of snake. From some facts recorded in Dr. Russell's History of Indian Serpents, on the authorities of Mr. Duffin and Mr. Ramsay, it appears that the Tanjore pill, of which arsenic is the chief ingredient, is exhibited with considerable success in India after the bites of venomous serpents. This information led Mr. Chevalier to propose the fair trial of arsenic.

Mr. Ireland, surgeon to the 60th regiment, had formerly heard Mr. Chevalier recommend the trial of arsenic, and he was resolved to make the experiment whenever an opportunity offered. On his arrival in the island of St. Lucia, he was informed that an officer and several men belonging to the 68th regiment had died from the bites of serpents, supposed to be the coluber carinatus of Linnæus.

The reader will find some interesting account of the serpent here alluded to, in a tract which I have lately read, entitled *Monographie du Trigonocéphale des Antilles, ou Grand Vipère Fer-de-Lance de la Martinique, par A. Moreau des Jonnés*, 8vo. *Paris*, 1816.

Mr. Ireland also learned that every thing had been tried by the attending medical men to no purpose, as all the patients had died, some in six, and others in about twelve hours from their receiving the wound.

A case, however, soon came under Mr. Ireland's own observations, and as nothing that had been done before seemed to have been of any service, he was determined to give arsenic a full trial.

"Jacob Course, a soldier in the York light infantry volunteers, was bitten in the left hand, and the middle finger was so much lacerated, that I found it necessary to amputate it immediately at the joint with the metacarpal bone.

I first saw him about ten minutes after he had received the wound, and found him in a torpid, senseless state; the hand, arm, and breast of the same side were much swelled, mottled, and of a dark purple and livid colour. He was vomiting, and appeared as if much intoxicated. Pulse quick and hard: he felt little or no pain during the operation.

The wound being dressed and the patient put to bed, I ordered a cathartic clyster, and the following medicine to be taken immediately. ℞. Liquor. arsenic ℥ ij. Tinct. opii gt. x. Aq. menth. pip. ℥ iss; which was added to half an ounce of lime-juice, and as it produced a slight effervescence, it was given in that state. This remained on his stomach, and was repeated every half hour for four successive hours. In the mean time, the parts were frequently fomented with common fomentations, and rubbed with a liniment composed of Ol. terebinth. ℥ ss., Liquor. ammon. ℥ ss., and Ol. oliv. ℥ iss. The cathartic clyster was repeated twice, when the patient began to be purged, and the arsenical medicine was now discontinued. He had become more sensible when touched, and from that time he gradually recovered his faculties; he took some nourishment, and had several hours' sleep.

The next day he appeared very weak and fatigued; the fomentation and liniment were repeated. The swelling diminished gradually; the natural colour and feeling returned, and by proper dressings to the wound, and attention to the state of his bowels, he soon recovered and returned to his duty."

Mr. Ireland recites about four other examples, in which arsenic was exhibited with similar success.

It deserves particular notice, that the liquor arsenicalis employed by Mr. Ireland was prepared according to Dr. Fowler's prescription, which directs sixty-four grains of arsenic and as many of the fixed vegetable alkali to be dissolved in a sand heat, and the solution to be made an exact pint, so that two drachms contain one grain of arsenic in solution.—(See *Med. Chir. Trans. vol. 2, p. 393, &c.*) Whatever may be the constitutional treatment of poisoned wounds, the local management of them on their first occurrence, according to the principles explained by Dr. Barry, and already noticed in this article, should never be neglected, as it is certainly most deserving of confidence. It operates as a preventive of symptoms, which, after they have come on, sometimes prove fatal. In hydrophobia this is too often proved.

[A singular case of poisoned wound from the bite of a rattlesnake occurred some years since, under the observation of Dr. S. T. Barstow, of Wilkesbarre, Pennsylvania, and in some respects is perfectly anomalous.

A lady in the fourth or fifth month of her pregnancy was bitten by a rattlesnake, but under the appropriate treatment she at length recovered from the symptoms usually consequent upon such wounds. At the full period of gestation, she was safely delivered of a fine, healthy-looking child; but immediately on its being applied to the breast and allowing it to suck, the child assumed the peculiar hues of the rattlesnake, swelled exceedingly, and soon died. She then procured a puppy to relieve her breasts, which died in two days of the same symptoms. A lamb was then tried; and in succession, one puppy and three lambs shared the same fate. Another puppy was then procured, which escaped with its life, but exhibited some of the symptoms which had been fatal to its predecessors. The lady remained all this time without any symptom of disease, and had as rapid a convalescence from parturition as is usually observed.

The poison seems to have been excreted by the process of lactation; for the second year afterward she had another child, and though she applied it to her breasts, not without fearful forebodings, yet no evil consequences resulted.

The obscurity in which the action of poisons on the human constitution is involved, is in nowise lessened when we consider that testimony of the most satisfactory sort shows that hydrophobia may be generated by *heat*, and that the disease may sometimes occur spontaneously. According to M. Unaniel, in 1807, in the village of Sea, forty-two persons died, after having been bitten by mad dogs; and on the north coast, hydrophobia occurred in several individuals without bite.—(See *Journal des Progres*, quoted in *North Am. Med. and Surg. Journ. vol.* 6.) The causes which may induce spontaneous hydrophobia are violent emotions of the mind, sorrow, fear, rage, fright, the want of food, &c. Drs. Hosack and Francis enjoyed a singular opportunity of witnessing a case of hydrophobia arising in a young man, aged thirteen years, independent of the bite of a rabid animal. He had been severely treated by his guardian or overseer for some imaginary offence; the want of food and clothing at an inclement season of the year could alone be looked upon as the exciting cause of his complaint. The symptoms of his disorder throughout were similar to those arising from madness induced by the bite of a rabid animal.—(*New York Med. and Phys. Journ. vol.* 2.) A curious paper on the various means employed for the cure of hydrophobia by Dr. Mease, may be seen in the Philad. Med. Museum; and though I have no confidence in the remedy, I must refer to Dr. Ramsay's paper in the Medical Repository of New-York, concerning the value of the volatile alkali in such cases.—(See farther *Thacher on Hydrophobia.*)—*Reese.*]

Wounds of the Thorax.—The thorax is a cavity of an irregularly oval figure, bounded in front by the sternum, laterally by the ribs, posteriorly by the vertebræ of the back, above by the clavicles, and below by the diaphragm, a very powerful muscle, which forms a kind of partition between the cavity of the thorax and that of the abdomen.

The diaphragm is not stretched across in a straight direction from one side of the chest to the other; but, on the contrary, descends much farther in some places than in others. If the cavity of the thorax be opened by a transverse section, about the middle of the sternum, the diaphragm appears, on examination, to be very prominent and convex towards its centre, while it sinks downward at its edges, towards all the points to which the muscle is attached. At its anterior and most elevated part, it is fixed to the ensiform cartilage, whence, descending obliquely to the right and left, it is inserted on both sides into the seventh rib, all the lower ribs, and lastly into the lower dorsal vertebræ. According to this description, it is obvious that the cavity

of the thorax has much greater depth and capacity behind than in front; a circumstance which surgeons ought to be well aware of, or else they will be liable to give most erroneous opinions concerning wounds of the chest. For instance, a practitioner deficient in anatomical knowledge might imagine, that a weapon pushed from above downwards into the front of the chest could never reach the lungs, after having penetrated the cavity of the abdomen. It is a fact, however, that no instrument could pass in this direction, even some inches below the highest part of the abdomen, without entering the chest.

The whole cavity of the thorax is lined with a membrane named the pleura, which is every where adherent to the bones which form the parietes of this cavity, and to the diaphragm. Each side of the thorax has a distinct pleura. The two membranes meet in the middle of the chest, and extend from the sternum to the vertebræ. In this manner, two cavities are formed, which have no sort of communication with each other. By the two pleuræ touching and lying against each other, a middle partition is formed, called the mediastinum. These two membranes are intimately adherent to each other in front, the whole length of the sternum; but behind, where they approach the vertebræ, they separate from each other, so as to leave room for the aorta, œsophagus, &c. The heart, enclosed in the pericardium, occupies a considerable space on the left of the mediastinum, and all the rest of the chest is filled with the lungs, except behind, where the large blood-vessels, nerves, thoracic duct, and œsophagus are situated. In the perfectly healthy state, the lungs do not adhere to the pleura; but in the majority of subjects, at least in this climate, who are examined after death, such adhesions are found in a greater or less degree. The disease may probably be occasioned by very slight inflammation; and as the surface of the lungs is naturally destined to be always in close contact with the pleura, and patients are frequently not suspected to have any thing wrong in the thorax, this morbid change being often accidentally discovered after death, in looking for something else, it may be concluded that it does not produce any serious effects.

The thorax is subject to all kinds of wounds; but their importance particularly depends on their depth. Those which do not reach beyond the integuments, do not differ from common wounds, and when properly treated are seldom followed by any bad consequences. On the contrary, those which penetrate the cavity of the pleura, even by the slightest opening, may give rise to alarming symptoms. Lastly, wounds injuring any of the thoracic viscera are always to be considered as placing the patient in a state of considerable danger.

From what has been said, it appears that wounds of the thorax are very properly divisible into three kinds: viz. 1, such as affect only the skin and muscles, 2, such as enter the cavity of the chest, but injure none of the viscera; 3, others which injure the lungs or some other viscus.

Superficial Wounds of the Thorax.—Immediately a surgeon is called to a recent wound of the chest, his first care should be to ascertain whether the weapon has penetrated the pleura or not. In order to form a judgment on this circumstance, surgical writers recommend, 1. Placing the wounded person in the same posture in which he was when he received the wound, and then carefully examining, with the finger or probe, the direction and depth of the stab. 2. The examination, if possible, of the weapon, so as to see how much of it is stained with blood. 3. The injection of fluid into the wound, and attention to whether it regurgitates immediately or lodges in the part. 4. The colour and quantity of the blood discharged from the wound are to be noticed, and whether any is coughed up. 5. We are to examine, whether air escapes from the wound in respiration, and whether there is any emphysema. 6. Lastly, the state of the pulse and breathing must be considered.

In wounds of the chest, however, surgeons should not be too officious with their probes, merely for the sake of gratifying their curiosity, or appearing to be doing something. No judicious surgeon can doubt that authors have dwelt too much on the subject of probing wounds of the abdomen and thorax; for they would really lead their readers to believe, that until the wound has been traced with the finger or probe to its very bottom and termination, surgeons are not qualified to institute any mode of treatment. The only advantage of knowing that a wound penetrates the chest is, that the practitioner immediately feels himself justified in having recourse to bleeding and other antiphlogistic means, with the view of preventing inflammation of the pleura and lungs, which affection, if not controlled in time, often proves fatal. However, there can be little doubt, that if the nature and depth of the wound cannot be readily detected with the eye, the finger or a probe, or by the discharge of air or blood, it is much safer to bleed the patient than to put him to useless pain with the probe, and waste opportunities of doing good which too frequently can never be recalled. In short, generally speaking, it is better and more advantageous for all patients, that some of them should lose blood, perhaps unnecessarily, than that any of them should die in consequence of the evacuation being omitted or delayed.

Almost all writers, who have taken pains to direct how wounds of the thorax should be probed, conclude with remarking, that however advantageous a knowledge of the direction and depth of the wound may be, much harm has frequently been done by pushing the attempts to gain such information too far. It is, perhaps of greater importance to learn by some kind of examination, the extent of a wound, which does not reach beyond the integuments or intercostals, than to know whether the wound extends into the cavity of the chest. For even when the pleura is found to be divided, if the wound be attended with no urgent symptoms, the information is of no practical use, if we make it a rule to adopt, without the least delay, a strict antiphlogistic plan of treatment in all cases, in which there is any suspicion or chance of the parts within the chest being wounded and likely to inflame. Besides, frequently the symptoms are more urgent and alarming than they could be, were only parts on the outside of the thorax injured; and under such circumstances, it is manifest that a probe cannot be necessary for discovering that the wound extends into the chest.

With respect to the injection of lukewarm water, or any other fluid, and the circumstance of its regurgitation as a criterion of the wound being only superficial, the plan is more objectionable than the employment of a probe; for if the liquid be propelled with force, it may be injected into the cellular substance, and seem to be passing through the track of the wound into the chest, while, in reality, not a drop does so. Besides, is it a warrantable proceeding to *try* to insinuate any quantity or kind of liquid whatever between the pleura and lungs, into a situation in which it must necessarily obstruct the important function of respiration, and cause serious inconvenience?

When air issues from the wound in expiration, there is ground for suspecting that the lungs are wounded. But I believe that such authors as represent this circumstance as an infallible criterion of the nature of the accident, labour under a mistake; for when there is simply an opening in the chest, without any injury of the lungs whatever, the same symptom may occur. The air which is discharged through the wound in expiration has previously entered the bag of the pleura through the same wound in inspiration. In order to remove all doubt, the patient may be requested to expire as strongly as he can, so as to force out whatever air may have accumulated in the chest. At the end of each expiration of this kind, care must be taken to bring the skin closely over the orifice of the wound, and to keep it thus applied during each following inspiration, for the purpose of preventing the external air from entering. In this way, if there be no wound of the lungs, all the air will soon be expelled; but if it still continues to be discharged in expiration, the lungs must be wounded.

Sometimes an emphysematous swelling takes place round wounds of the thorax, in consequence of a quantity of air diffusing itself in the cellular substance. In wounds which are straight and ample this symptom is very uncommon, but in cases of narrow oblique stabs, and where the lungs are wounded by the points of broken ribs, it is by no means unfrequent.—(See *Emphysema.*) When a considerable quantity of blood flows from the wound, there is reason for conjecturing not only that the weapon has penetrated the cavity of the thorax, but that some of the thoracic viscera are injured. Excepting the intercostal arteries, which run along the edges of the lower ribs, and the trunks of the

thoracic arteries, all the other vessels on the outside of the chest are very inconsiderable. The effects of compression will indicate whether the blood escapes from an artery on the outside of the cavity of the pleura; and sometimes the situation and direction of a wound at once denotes that the hemorrhage cannot proceed from the trunks of the thoracic arteries.

Even the appearance of the blood which comes from the wound may lead to some conjectures concerning the depth of the injury. The blood which flows from wounds of the lungs is of a brighter scarlet colour, and more frothy than that which is discharged from the vessels of any other part.

There can be no doubt of the lungs being wounded, when the patient is observed to spit up blood; but the absence of this symptom is not a positive proof of their being untouched, though unquestionably a very important circumstance in the diagnosis, and, generally speaking, a correct criterion of the lungs having escaped injury. At all events, when no blood is spit or coughed up, the lungs can never be deeply penetrated.

The state of the pulse and that of respiration, ought to be particularly attended to by the practitioner. Neither one nor the other seems altered, at least at first, when wounds do not reach more deeply than the integuments: but those which penetrate the cavity of the thorax, and especially such as injure the viscera, may frequently be distinguished from the very first moment of their occurrence, by their effects on the sanguiferous system, and the function of respiration. When the lungs are wounded at a point where they adhere to the pleura, no air can be effused in the thorax, and the functions of those organs may on this account suffer less disturbance than would be the consequence of an equal degree of injury at some other unadherent portion of the lungs. Experience proves, that when either air or blood insinuates itself between the lungs and the pleura, the lungs become immediately oppressed, the breathing is attended with great difficulty, the pulse is weak, contracted, and intermittent.

Wounds of the integuments and muscles of the thorax are not attended with any particular danger; they heal with the same readiness, and by the same means, as common superficial wounds in any other part of the body.

When the case is a punctured or a gun-shot wound, some writers are advocates for laying open the track of the injury from one end to the other, if its course should not be too extensive, and they then recommend dressing the cavity down to its bottom. When the track of the wound was too extensive, a seton was sometimes introduced. The aim of such exploded practices was to prevent the outer part of the wound from healing too soon, and thus give time for the whole of it to heal in an equal degree. When a seton was used, the thickness of the skin was gradually diminished, and after the whole of it had been removed, a slight compression was kept up for a few days, with the view of completing the cure.

The French surgeons have the discredit of having brought setons into fashion in this branch of surgery; and I am particularly glad that a late writer has well exposed the absurdity of the practice. "We find (says Mr. John Bell) the history of it to be plainly this: that as Guy de Chauliac, Paré, and all the older surgeons, did not know how to dilate gun-shot wounds, they found these same setons useful in bringing the eschar sooner away, and in preserving an open wound; and as they believed the wounds to be poisoned, they took the opportunity of conducting, by these setons, whatever acrid medicines might, according to the prevailing doctrines of that time, have any chance of correcting the poison." Mr. J. Bell notices, how surprising it is to see the cruelty and perseverance with which some modern practitioners, particularly French, draw these cords through wounded limbs; and when the roughness of such a cord, or the acrimony of the drugs conveyed by it, produces a copious suppuration, these men are delighted with such proof of their success. The setons have been introduced by the French surgeons, across the thickest parts of the limbs, along the whole length of the forearm, and at the same time frequently through the wrist-joint. The setons have also been covered with stimulating applications. Profuse suppurations and dreadful swellings, of course, ensued; still, as Mr. J. Bell has remarked, these cruelties were continued till the wound healed almost in spite of the pain: or till the coming on of very dreadful pain, great suppurations, convulsions, &c. made the surgeon discontinue the method, or even amputate the limb. The French have become so familiarized to setons, that they do not restrict their use to flesh wounds; they pass them quite across the thorax, across the abdomen, and even through wounds of the knee-joint.

When we wish to excite inflammation in the cavity of the tunica vaginalis, for the purpose of radically curing a hydrocele, we either pass a seton through the part; lay it open with an extensive incision; cram a tent into it; or inject some irritating fluid into it. While the animal machine continues the same, says Mr. John Bell, the same stimuli will produce the same effects, and a seton, injection, or long tent, if they produce pain or inflammation in the scrotum, will not be easy in the chest; and unless we can use them in the chest, with the same intentions with which we use them in the hydrocele, in other words, unless we are justified in inflaming the chest and causing an adhesion of all the parts, we cannot use them with any consistency or good sense.

With regard to the cases which the French adduce in confirmation of the good effects of their plans, I am entirely of opinion with Mr. J. Bell, that the facts only prove, that the *patients recovered in spite of the setons.* "It is like (adds this author) what happened to a surgeon who was dabbling in the thorax with a piece of caustic, which fell directly into the cavity of the chest, where it caused very large suppurations, and yet the patient was saved. The patient recovered in spite of the caustic, just as M. Guerin's patient, and many other poor unhappy souls, who lived in spite of the setons. One would think that people took a pleasure in passing setons across the eyeball, the chest, the knee-joint, &c. merely to make fools stare, when the business might be as effectually done with an abscess lancet."

Mr. John Bell, in his usual lively style, makes the employment of tents, in wounds of the chest, seem equally ridiculous and improper. Indeed, he says, *he knows of no occasion in all surgery in which tents can be useful, except in the single one of a narrow opening which we desire to dilate, in order to get at the bottom of the wound; and where, either on account of some great artery, or the fearful temper of our patient, we dare not use the knife.*—(See *J. Bell on Wounds. Discourse* 2, *vol.* 2.)

Having hitherto been engaged rather in pointing out what ought not to be done, than what ought, I shall next make some remarks on the line of conduct which should be adopted in cases of wounds of the parietes of the chest.

When the wound is a common cut, the sides of the division are to be brought into contact, and maintained in this position with strips of adhesive plaster, compresses, and a bandage, until they have grown together. If the surgeon take care to relax such muscles as happen to be cut, or to be situated immediately under the wound of the integuments, there will rarely be any need of sutures.

As cut wounds seldom or never penetrate the chest, and there is generally no reason why they should not unite by the first intention without being followed by extensive inflammation and abscesses, antiphlogistic means should be employed with moderation. Bleeding will not often be requisite. The grand objects are to keep the patient in a quiet state, on rather a low diet, and to hinder him from taking wine, porter, spirits, or any other stimulating beverages.

If the wound, instead of healing favourably, should inflame, the treatment must be regulated by the principles laid down in the article *Inflammation.* If it suppurate over its whole surface, but without a great deal of surrounding swelling and inflammation, one or two strips of sticking plaster may still be used with advantage; for in this way the cavity, which must now be filled up by granulations, will be rendered much smaller than it otherwise would be. Some very soft lint may be laid in the cavity of the wound, which the sticking plaster does not entirely remove, and over the whole a pledget of some mild, unirritating ointment. No pressure is now proper, until the inflammation diminishes; and if the discharge should be profuse, or the surrounding inflammation considerable, the best application would be an emollient poultice. In this state of things the patient should also be bled, and leeches be applied near the inflamed parts.

When the case is a stab or punctured wound, the fibres of the divided parts are not simply cut, they are also considerably stretched, bruised, and otherwise injured. Hence, generally, they will not admit of being united so readily as the sides of a clean incision, made with a sharp instrument. However, the possibility of uniting the opposite sides of punctured wounds must depend very much on the shape of the weapon, and the suddenness, roughness, and violence with which it was driven into the part. A prick with a needle is a punctured wound; so is that often made by surgeons with their lancets; yet these injuries do not frequently bring on violent inflammation and abscesses, as other wounds frequently do which are inflicted with bayonets and pikes.

Let us suppose a man to have received the thrust of a bayonet, which has run into the skin and muscles covering one side of the thorax: what plan can the surgeon follow with the greatest advantage to his patient?

Instead of laying open the whole track of such a wound with a knife, as is barbarously recommended in many of the works on surgery; instead of drawing a seton through its whole course, or of cramming into the part a hard irritating tent; the practitioner should take whatever chance there may be of uniting the wound without suppuration. For this purpose, he should recollect that the great degree of violence done to the parts in punctured wounds is the reason why they are so apt to inflame and suppurate. Hence, the expected inflammation is to be counteracted in the very first instance; and immediately the wound is dressed, the patient should be freely bled, and take some saline purgative medicines. With regard to the dressings, the orifice of the wound may be lightly closed with sticking plaster, or covered with any mild superficial applications. Over and around these the surgeon may apply linen, kept continually wet with cold water or the liquor plumbi acetatis dilutus. As, however, many patients have a strong dislike to cold applications to any wounds upon their bodies, it is often necessary to dispense with this practice. The dressings are to be retained with a roller; but it is not to be tight, as pressure is more likely to do harm than good. Thus, the inflammation of the wound will be moderated; the extravasation of blood prevented; the chance of union by the first intention taken; and all painful operations avoided. And nothing is more certain than the fact, that if antiphlogistic means be strictly employed, many stabs heal without abscesses, or any very severe symptoms, when no hope could be entertained of their doing so under other treatment. But if suppuration should happen, and a collection of matter take place, would the patient suffer more or be put into greater danger by having a proper depending opening of just sufficient size, now made into the abscess in an eligible place, than if he had submitted to have the formidable operation of laying open the whole extent of a stab performed in the first instance? In short, will he suffer half so much, be half so long in getting well, or have to encounter half the danger? With all this advantage, he will have taken a certain chance which attends all these cases of the wound becoming united by what is called the first intention; that is to say, without any suppuration. I need not enlarge upon this subject, but refer the reader to what has been said in the preceding columns on the subject of *Punctured Wounds*, and to the treatment of abscesses, in the article *Suppuration*. Gun-shot wounds merely injuring the parietes of the chest are to be treated according to principles elsewhere explained.—(See *Gun-shot Wounds*.)

Of Wounds penetrating the Cavity of the Thorax.—Penetrating wounds of the chest are always dangerous, and claim the utmost attention of the practitioner. I shall first treat of such wounds as enter the cavity of thorax, but without injuring the viscera.

In the healthy state, the lungs so completely fill the thorax, that, both in inspiration and expiration, they are always in close contact with the pleura; and whenever air, blood, or any other matter insinuates itself between the pleura costalis and pleura pulmonalis, more or less oppression and difficulty of breathing immediately take place. In all wounds attended with a division of the pleura costalis, and occurring in a situation where there happens to be no adhesion between this membrane and the lungs, some of the external air, or a small quantity of blood, or both, can hardly fail to get into the cavity of the thorax. If one of the intercostal arteries be wounded, and the external orifice be very narrow, the blood furnished by this vessel may pass into the chest, and immediately produce oppression of the breathing, and other symptoms of pressure on the lungs. Of what is to be done in this case, I shall presently speak.

When a wound is known to have entered the pleura, and there is no symptom leading to a suspicion that the lungs or any large vessel is wounded, the injury is to be dressed according to common principles, and the more superficially the better. Authors also usually direct us, just before we close the opening, to tell the patient to make a deep inspiration, for the purpose of expelling as much of the air as possible which may have passed into the cavity of the pleura. At the end of such inspiration, the edges of the wound in the skin are to be brought together and kept so with sticking plaster, compresses, and a roller. The other indications are to prevent inflammation of the pleura and lungs, by rigorous antiphlogistic remedies, particularly bleeding, which should be copious, and repeated as circumstances may require.

Penetrating wounds of the chest may be complicated with some of the following circumstances: 1. Foreign bodies. 2. Injury of one of the intercostal arteries. 3. Protrusion of a portion of the lungs. 4. Emphysema. 5. Extravasation of blood in the thorax.

1. Almost all these wounds occasion pain and difficulty of breathing. Many of them are also followed by an emphysematous swelling around the wound; the patient frequently coughs up blood; and after having had for some time a small, contracted, irregular pulse, with a pallid countenance and cold extremities, he is too often seized with severe febrile symptoms, the effect of inflammation of the lungs and parts within the chest. These symptoms should be counteracted by bleeding, a very low regimen, opening saline medicines, the use of leeches, or cupping, and the strict observance of quietude. If such indisposition should continue longer than a few days without diminution, writers inform us that there is ground for suspecting that they depend upon the presence of some foreign body. However, it may be doubted whether Sabatier's advice, immediately to make search after the extraneous substance, is proper, under these circumstances. For my own part, I cannot think the symptoms above related by any means unequivocal, and even were they so, the practice would still be questionable.—(See *Médecine Opératoire, t. 2, p. 244.*)

Sabatier has quoted the two following cases, for the purpose of showing what may be attempted in these cases. "A man, twenty-seven years of age, was struck very violently with a knife on the outer part of the fourth true rib. Simple dressings were applied for the first few days; but a considerable coughing and spitting of blood ensuing, M. Gerard was consulted, who found that the symptoms depended on the presence of a piece of the knife, which had pierced the rib and was projecting some way into the thorax. So little of the foreign body was on the outside of the rib, and it was so fixed in the bone, that it could neither be extracted with any kind of forceps, nor even moved in the least with a leaden mallet, &c. Although the only expedient seemed now to be that of sawing or cutting out a portion of the rib, Gerard conceived that an attempt might first be made to extract the foreign body by pushing it from within outwards. For this purpose, having put a steel thimble on his index finger, he introduced it into the cavity of the thorax, and thus succeeded in pushing out the piece of the knife.

A spicula of the bone was afterward felt; but it was too firmly connected with the rest of the rib to admit of being completely taken out. Gerard was absurd enough to *surround the whole rib at the splintered part with a ligature.* To these ingenious proceedings, as the French term them, was imputed, not only the cessation of all the bad symptoms, but a speedy recovery.—(See *La Faye's Notes to the Traité des Opérations de Dionis.*)

An officer was shot in the left side of the chest. The ball entered about where the bone and cartilage of the seventh true rib unite, and came out in the situation of the angle of the same bone, which was broken in two places. The posterior part of the first false rib was also broken. Incisions were made which enabled the surgeon to take away several splinters of bone, and facilitated (that mischievous French practice) the intro-

duction of a seton. Soft mild dressings were applied. The patient was bled twenty-six times, with the view of relieving the fever, difficulty of breathing, and spitting of blood. On the fifth day, suppuration commenced and the seton could be easily drawn. In about a fortnight, the patient's sufferings considerably abated, and he passed some of the ensuing days in a tolerably easy state. Circumstances, however, made it necessary to remove him to another place, and on the twenty-fourth day he had a bad night; febrile symptoms came on; and the discharge was not of its usual consistence. He was bled twice more, and his critical state led the surgeon to examine the wounds again. On passing a finger into the posterior wound, a foreign body was felt and easily extracted. It was a piece of the patient's coat. A spicula of bone was also felt more deeply lodged, which required the wound to be dilated. Partial relief followed the removal of these extraneous substances.

On the thirtieth day the bad symptoms recurred, two more bleedings were practised, and, *as fears were entertained that the seton was doing harm*, it was suppressed. The patient now first made complaint of feeling something which pricked him in a deep situation, between the two openings of the wound. It was therefore determined to divide all the parts intervening between the two orifices, and occupying an extent of seven or eight inches. Guerin cut the parts between the two ribs from within outwards, under the guidance of his finger introduced into the posterior wound, care being taken not to cut near the lower edge of the upper rib. In this way, the whole track of the ball was laid open, and in the middle of it a very sharp splinter was found, projecting into the substance of the lungs. It was removed, and the wound dressed with simple applications. From this day all the bad symptoms ceased. —(*Obs. de Guerin in Mém. de l'Acad. de Chir. t.* 2, 4*to.*)

Mr. John Bell has taken notice of the preceding case; he observes, that some of Guerin's steps were bold and good, as well as successful; but that the employment of the seton was wrong. The example teaches us several important circumstances: 1. The propriety of making very free dilatations for the extraction of splinters of bone. 2. The utility of repeated copious bleedings, which, in the above case, indeed, had the greatest effect both in preventing such hemorrhage in the chest, as would probably have produced suffocation, and also in averting a degree of pulmonary inflammation, which would have proved fatal.

Mr. John Bell judiciously condemns the seton: "Had M. Guerin (says he) been asked what good it was to do, it would have been difficult for him to have invented even a plausible apology for the practice, which, if it was not doing good, could not fail to do harm. Was this seton necessary for keeping the wound open? No, surely, for the wound could not have closed while it was irritated and kept in suppuration by splinters of bone, and a piece of cloth within the breast. Was it to draw the piece of cloth out? Surely, in the course of twenty days, a piece of cloth would have had some chance, at least, of being floated towards the wound, either by the natural flux of the matter, or by the help of a mild injection. Was it useful in supporting the discharge? This would have been a sore question for M. Guerin; for it supported the suppuration only by inflaming the chest; and where inflammation of the chest, or high cough, or bloody expectoration, or a profuse discharge were the chief dangers, a great seton could hardly be a comfortable inmate in the breast. I think one might very boldly promise to produce bloody expectoration and terrible cough, profuse suppurations, and oppression to any degree, by drawing such a cord across a sound thorax."

Mr. John Bell next censures M. Guerin for not having discovered the pricking piece of bone before the thirty-eighth day; a disadvantage which he partly ascribes to the seton, the pain of drawing which across the chest deadened every less pain, and, consequently, the patient could not feel the trifling pricking of the bone, till his greater sufferings from the seton were allayed. "In short (says Mr. John Bell), M. Guerin passes a great strap of coarse linen across the cavity of the chest, and when it causes inflammation, he thinks to subdue it by bleeding; when M. Guerin continued for thirty days drawing a coarse seton through the breast every morning, and bleeding for the cough every night, what did he do, but raise inflammation with his left hand, to show how well he could cure it with his right."—(See *John Bell, On Wounds*, vol. 2, *p.* 36—38.)

The liability of wounds of the chest to be complicated with the lodgement of foreign bodies, is a circumstance of which the practitioner should ever be mindful. "In the examination of the bodies of soldiers who have died from these injuries (says Dr. Hennen), I have frequently found pieces of wadding or clothes, spiculæ of bone, and balls, and, in one case, some charpie used as a dressing; either loose in various parts of the lungs, or lying in sacs, which the exertions of the constitution to free itself had thrown round them by the medium of the coagulating lymph. In the more fortunate few who have recovered, these matters have been discharged from the wounds, or extracted from them by the surgeon. In some lucky cases, they have been ejected by the convulsive efforts to cough, which their irritation has occasioned."—(*On Military Surgery, ed.* 2, *p.* 367.) For an account of the dexterity with which Larrey has sometimes traced balls in the chest, and extracted them by bold operations, I must refer to his valuable writings.—(See *Mém. de Chir. Mil. t.* 4, *p.* 250, *&c.*) Balls have sometimes lodged and remained encysted in the lungs for upwards of twenty years, without the health being at all disturbed by their presence.—(See *Percy, Manuel, &c. p.* 125; *Boyer, Traité des Mal. Chir. t.* 7, *p.* 310, *&c.*)

2. When one of the intercostal arteries is wounded by a narrow oblique stab, the accident cannot at first be known. In this case, the blood commonly makes its way into the cavity of the chest, where it causes a more or less considerable extravasation. But when the wound is ample and direct, the effused blood, which has all the characters of arterial blood, leaves no doubt concerning the injury of an intercostal artery. However, if any uncertainty prevail, it may easily be dispelled by introducing a finger into the wound, and making pressure with it on the lower edge of the rib, which corresponds to the vessel suspected to be injured.

Gerard proposed to stop hemorrhage from the intercostal artery by means of a ligature. His plan was to enlarge the external wound as far as the upper edge of the rib, corresponding to the wounded intercostal artery, and then to introduce into the chest a common curved needle, armed with a ligature, to which was attached a dossil of lint. The needle was passed behind the rib, rather higher than the superior edge of the bone. The point of the instrument was then pushed from within outwards, and brought out through the external wound together with the ligature. When the dossil had come into contact with the artery, the two ends of the ligature were tied over a thick compress, placed on the outside of the rib. In this manner, the bone was surrounded with the ligature, and the artery compressed.

Goulard, of Montpellier, having found difficulty in passing a common needle, whose shape little corresponded to the track through which it had to pass, being curved towards its point, and straight towards the eye, invented one expressly for this operation. He also objected to the common bent needles, as he conceived that they might wound the lungs with their sharp points and edges. Goulard's needle formed three-fourths of a circle, and was fixed on a long handle, which facilitated its introduction. The eye, in which the ligature was put, was situated near the point, which was a little blunted, and the ligature lay in a groove in the convexity of the instrument. When the needle had passed through the intercostal muscles, and its point had made its appearance over the rib, which was above the artery, the ligature was untied, and held, while the needle was withdrawn at the place where it had entered. The ligature was then tied, as in Gerard's method.

It was afterward thought, that compression might answer better than the foregoing use of the ligature. Lôttery, professor of anatomy in the university of Turin, constructed for this purpose a steel plate, which is described and engraved in the second volume, 4to. of the *Mémoires de l'Acad. de Chir.* This plate was narrow at one end, broad at the other, and curved in two directions at its narrow part, where there were some holes, by means of which a compress for the artery was fastened on the instrument. The broad end of the plate had two long parallel slits, through which a riband was passed, with which the instrument was secured.

When the wound corresponding to the intercostal artery was sufficiently extensive in the transverse direction, the narrow, bent end of the instrument was so introduced, that the lower edge of the rib above was placed in the concavity of the curvature, while the compress acted on the edge of the bone, and, of course, on the artery. The rest of the instrument applied itself to the side of the thorax, in which situation it was fastened. When the wound was not ample enough, a sufficient dilatation of it was first made for the introduction of the instrument.

Quesnay employed a piece of ivory, which he covered with lint, &c. and introduced within the chest. The instrument was then drawn from within outwards by means of a riband, and thus the necessary compression was produced.

Quesnay's plan is somewhat like that invented by Löttery. But to have introduced the compress entirely into the thorax, together with the ivory, which was the basis of it, and then to have drawn the contrivance from within outwards, as was probably intended, a very large wound would have been indispensable. This was also one of the many strong objections to Löttery's instrument, which, in fact, could only be employed when there was a free and ample opening.

Belloque, seeing the inefficacy of all the compressing means used before his time, and their inconveniences, invented an instrument, which, he says, is calculated for making proper pressure, and following the motion of the ribs without hindering the escape of extravasated blood. The machine is engraved and described in 2 t. of *Mém. de l'Acad. de Chir.* 4*to*. It is composed of two plates, which are wadded, and capable of being brought towards each other by means of a screw. This instrument, as Sabatier observes, may indeed answer; but it is complicated and awkward, and its utility is founded on the supposition of the wound being larger than wounds are which are made with common weapons.

Justly averse to any unnecessary multiplication of surgical instruments, modern practitioners reject all particular contrivances for stopping hemorrhage from the intercostal arteries. Indeed, as the accident is very rare, it is probable, that if the best instrument possible were devised it would hardly ever be at hand when required.

A common dossil of lint (says Sabatier), fastened to a strong ligature, and introduced between the two ribs, or even quite into the chest, and then drawn from within outwards like Quesnay's compress, would fulfil every desirable purpose. The external wound should then be covered with simple dressings, and a bandage applied round the body. The patient should be freely and repeatedly bled, and treated on the most rigorous antiphlogistic plan.

Professor Assalini joins all the best modern surgeons in reprobating the introduction of the preceding contrivances and extraneous substances into the chest, in order to stop hemorrhage from the intercostal artery. All these methods, he remarks, are calculated to excite a dangerous degree of inflammation in the chest. Hence, he prefers simply cutting the artery across, so as to allow it to retract, and, if this plan fail, he recommends the wound to be closed. Should the blood find its way into the chest, it is true, the consequences will be serious, but not fatal; and if the symptoms require it, the operation of empyema may afterward be done. A small quantity of effused blood, however, may be absorbed, and no such proceeding be requisite. —(*Manuale di Chirurgia*, *p.* 58, 59.)

Dr. Hennen conceives, that whenever the tenaculum *can* be used for an injured intercostal artery, the practice should be adopted. He states, that cases are reported in which the vessel was thus secured; but that he has never seen the method adopted himself. "Unfortunately (says he), we but too often are disappointed in finding the source of the hemorrhage, and here judicious pressure is our only resource. In some very slight cases, I have used the graduated compress with success; but, if the sloughing is extensive, nothing but the finger of an assistant, relieved as often as occasion may require, and pressure direct upon a compress placed along the course of the vessel, or so disposed as to operate upon its bleeding orifice, will be of any avail." —(*Military Surgery*, *ed.* 2, *p.* 377.)

3. The protrusion of a portion of the lungs, in consequence of wounds penetrating the chest, is a very unusual case; but there are some instances recorded by writers, and one case I attended myself after the battle of Waterloo. Schenckius relates an example taken from Rolandus. The latter was called to a man who had been wounded in the thorax six days before. A portion of the lung protruded, in a state of mortification. Rolandus extirpated it, and the patient soon recovered.

Tulpius has recorded a similar fact. A man received an extensive wound just below his left nipple. His naturally gay disposition, however, led him to neglect the injury: and on the third day, a piece of the lungs, three inches in length, protruded. The patient went to Amsterdam, whence he was distant two days' journey, for the purpose of receiving succour in one of the hospitals of that city. The protruded piece of lung, which was already mortifying, was tied, and cut off with scissors. It weighed three ounces. The wound healed in a fortnight, and the patient experienced no complaint afterward, except a slight cough, with which he was occasionally troubled. He survived the accident six years, leading a wandering, drunken life. After death, nothing particular was observed in the thorax, except that the lungs had become adherent to the pleura, in the situation of the wound. Hildanus relates another case. A man was wounded with a knife between the fifth and sixth ribs, near the sternum. As a piece of lung protruded at the opening and was of a livid colour, it was extirpated with the actual cautery. The wound was then dilated, and the ribs kept apart with a wooden wedge, under which plan the portion of lung girt by the opening shrunk within the chest. The patient was soon completely well.

A fourth example of a protrusion of a piece of lung through a wound in the thorax, is among the cases recorded by Ruysch. The servant of a seafaring man was wounded in the anterior and inferior part of the chest, and was immediately attended by a surgeon, who mistook the protruded piece of lung for a portion of omentum, and applied a tight ligature round it. Ruysch, who was consulted, soon detected the mistake which had been made; but he delivered his opinion that the wound would heal very well, as soon as the tied piece of lung was detached. The event justified his prognosis, and the patient recovered.

When the protruded portion of lung is sound, the reduction ought to be made without the least delay. It should be done on the same principles as those on which protruded pieces of intestine, or omentum, are reduced.—(See *Wounds of the Abdomen.*) A recurrence of the accident is to be prevented by closing the wound, and placing a compress over it. But when the piece of lung is already in a mortified state in consequence of the constriction which it has suffered, or when its large size prevents reduction, Sabatier is of opinion that the only resource is to extirpate the part, after applying a ligature round its base. If the latter step were not taken, a dangerous hemorrhage might follow, or even an extravasation in the thorax.—(*Médecine Opératoire*, *tome* 2, *p.* 224.) However, the practice recommended by Sabatier appears questionable in the instance of mortification, because the dead part will naturally be thrown off by a spontaneous process; and when the wound is too small to allow the part to be returned, its dilatation might be more advisable than the removal of a considerable portion, or even any, of the lung.

After the battle of Waterloo, I had a patient with a protrusion of a piece of lung, four or five inches in length. The part was much bruised, and could not be easily reduced. I therefore applied a ligature round its base, and cut it off. Previously, however, I made an incision in it, in order to ascertain whether it would bleed freely, which being the case, induced me to use a ligature. I was afterward informed by my friend, Mr. Collier, that the man died.

4. Emphysema is another symptom with which penetrating wounds of the chest are frequently complicated, especially when they are small and indirect. When such wounds are small, and not straight in their course; when their track is rendered impervious, either by change in the situation of the muscles, the swelling of the parts, clots of blood, or any extraneous substances; air may insinuate itself into the cellular substance, so as to cause a great deal of tumour and dis-

tention. Emphysema is easily distinguishable by the tumefaction of the part affected, without any pain, or change of colour in the skin, and by the crepitation which is perceptible on pressing the air from one part of the cellular substance into another. Emphysema may take place where the lungs are not wounded; but in this case it can never be of much extent. Here the emphysematous swelling is caused by the air which insinuates itself into the cavity of the thorax through the wound, during the first inspirations which follow the accident, and the same air is expelled in the subsequent acts of expiration. But when the lungs are wounded, the emphysema arises from the escape of air from those organs during inspiration, first into the cavity of the thorax, and thence, through the inner opening of the external wound, into the cellular substance.

I should have deemed it unnecessary to have said any thing in this part of the work on the present subject, and have contented myself with referring to the article *Emphysema*, were not the cause of this symptom rather perplexing, and did I not hope that the following extract from Sir A. Halliday's publication will tend to facilitate the comprehension of these cases. This gentleman mentions the following circumstances, under which air may escape from the lungs, or emphysema arise.

1st. "An injury or disease of the pleura pulmonalis, causing a wound or ulceration of that membrane, and thus allowing the air to escape from the lungs, as in oblique external wounds, where the outer opening and that of the pleura costalis have healed, or closed up, and in ulcers of the surface of the lungs.

2dly. That pleura pulmonalis and pleura costalis may be wounded or ulcerated, when there is no external opening, as when the ends of fractured ribs penetrate through both into the substance of the lungs; and it is from this accident, &c. that emphysema most commonly takes place.

3dly. The common integuments of the parietes of the chest, the intercostal muscles, and the pleura costalis may be wounded, while the pleura pulmonalis and the lungs remain uninjured; so that the air admitted from without and collected in the cavity of the thorax, may be pressed into the cellular membrane, so as to occasion emphysema."

The same writer remarks, "that the lungs in the thorax have often, and not inaptly, been compared to a bladder in a close pair of bellows; but if we suppose the bellows to be divided into two compartments, and each of these to contain a bladder, which mutually communicate with each other and with the external air, by means of a tube, which is exactly adapted to the nozzle of the bellows, and which admits the air only into the cavity of the bladders, and not into the space between the bladders and bellows, we shall then have a perfect representation of the mechanical structure of the thorax. The bellows will represent the thorax, divided in the middle by the mediastinum; the bladders will represent the lungs of the right and left sides; and the tube which communicates with the bladders and with the external air, will represent the trachea. The only thing which is wanting to render this mechanical representation perfect is, that the bladders should exactly fill the bellows, so as to leave no air between them and the bellows."

It is explained by Sir A. Halliday, that when the handle of the bellows is lifted up, the bladders become filled by the external air, which rushes in through the tube which communicates with both of them. When the handle is depressed, the air is expelled again. In the like manner, the lungs are filled with air, and emptied again when the capacity of the chest is enlarged by the inspiratory muscles, and then diminished by the expiratory ones.

When emphysema arises from a wound or ulceration of the pleura pulmonalis, on one side of the thorax, the case is nearly the same as if an opening were made in one of the bladders, which opening would form a communication, as the same gentleman observes, with the bellows and bladder on one side. If this should happen while the handle of the bellows is depressed, no sooner is the handle raised, than air rushes into the space between the bladder and bellows; and on keeping up the handle a little while, the bladder will become quite collapsed, and the place which it occupied, while distended, will now be occupied by the air. "If now (says Sir A. Halliday) we attempt to force out the air by depressing the handle of the bellows, we shall find that this cannot be done; for there is no direct communication between the bellows and the external air; and as the effused air presses equally on all parts of the collapsed bladder, it cannot escape through it."

When the thorax is expanded in inspiration, the pressure is taken off the surface of the wounded lung, and the air which now enters this organ, instead of distending its cells, passes through its wound into the space between the pleura pulmonalis and pleura costalis. The lung will, indeed, be partially expanded, as long as inspiration on that side goes on; the more so, the smaller its wound is. At every expiration, however, when the thorax is diminished, the effused air will be compressed against the wounded lung; but none of the air which has escaped can re-enter the lung again; "because (as the preceding writer accurately remarks) the whole of the air contained in the lung must be forced out, and then the pressure (of the air) against every part of the collapsed lung being equal, will prevent its separating any part, so as to make a passage for itself into the trachea." Thus fresh air accumulates at every inspiration in the space between the pleuræ, while none can escape from the same situation during expiration; and the quantity accumulated will at last equal that which is received into the other lung during the most powerful inspiration.

When the pleura pulmonalis and pleura costalis are both wounded, the same effusion of air between them continues from the above-mentioned causes, till the lung collapses. When an attempt is now made to expire, the injured side of the thorax must continue distended, notwithstanding every effort of the patient In this expiratory act, however, if the capacity of the thorax be diminished, and the air compressed, a part of it finds its way through the wound in the pleura costalis, into the common cellular substance of the parietes of the chest.

The passage of air into the cavity of the thorax during the inspiration is, as Sir A. Halliday observes, now more easy than the return of that already effused in the cellular membrane; and, consequently, the *subcutaneous emphysema* continues to increase with a rapidity which is remarkable, as long as the patient lives.

To explain the origin of emphysema in cases of wounds which only enter the chest and do not injure the lungs at all, this writer has recourse to the simile of the bellows and bladders. Were an opening made into the bellows without injuring the contained bladders, and the access of air by this opening more free than that by the nozzle, communicating with the cavity of the bladder, more air would enter by the opening than by the pipe, on the handle being raised; so that the bladder would not rise as usual, when no opening in the side of the bellows existed. If the latter opening be smaller than that of the pipe, the bladder will only be partially filled; and on depressing the handle of the bellows, the air contained in the bladder, and that between the bladder and the bellows, will be expelled in the same proportion to each other as that in which they were formerly filled. This process would continue to go on in the same way, did not the bladder naturally collapse more and more from its gravitation. Let us now stop the mouth of the pipe, while the handle of the bellows is raised, and the bladder partially filled. On trying next to depress the handle, it results that, as no air can escape from the pipe, the air contained between the bladder and the bellows must be first evacuated, while that contained in the bladder of the sound side will be forced into the bladder on the injured side, and either distend it, so as to rupture it, or cause it to protrude.

Hence, in the case of a wound penetrating the chest without injuring the lungs, if the air can enter more freely by the wound than by the trachea, more of it will enter, in the act of inspiration, into the cavity of the thorax than into the lungs. On the contrary, when the opening of the wound is not so large as that of the trachea, less air will enter the thorax than the lungs.

In the expiration, the air will be forced from the two different situations in proportion to the quantity which enters each of them in inspiration, and no air at all would accumulate in the thorax, did not the lungs always tend to collapse from their gravitation. Should

however, the patient, in making an effort to expire, contract the glottis, the air contained in the lungs of the sound side may be propelled into the bronchia and air-cells of the lungs, on the same side as the wound, so as to distend them, and even make them protrude at the wound.

Dr. Halliday remarks, that such a protrusion often happens when wounds are made in dogs, and has been erroneously adduced as an argument against the collapse of the lungs, when an opening is made into the thorax of the human subject.—(See *Obs. on Emphysema, by Sir A. Halliday*, 1807.)

For information concerning the treatment of this affection, see *Emphysema*.

5. I have already noticed, that wounds of the thorax may injure one of the intercostal arteries, and when the blood cannot flow outwards it may be extravasated in the chest. The same consequence may follow wounds of the pulmonary vessels, those of the heart, or of the heart itself. And here I may take the opportunity of remarking, that sometimes wounds of the heart do not prove instantaneously fatal. A case, in which a bayonet passed through the colon, stomach, diaphragm, part of the lungs, and the right ventricle of the heart, and yet the patient lived nine hours after the receipt of the injury, is recorded by Dr. Babington. —(See *Med. Records and Researches. Lond.* 1798; *also, a case by Chastenet, in Journ. de Méd. Mil. t.* 2.) In almost all cases, however, such injuries prove instantly fatal; and the same remark will extend to cases of hemorrhage from vessels above a certain size, but when they are less considerable, the patient may live for a greater or less time and receive the aid of surgery.

[Though wounds of the heart are deemed necessarily fatal, they do not always immediately prove so. Our medical records contain various cases in proof of this: very recently a case of murder came before the Criminal Court of New-York, in which the medical witnesses in behalf of the people affirmed, that the deceased, as proved upon the examination of the body, had received the fatal wound in the left ventricle of the heart; yet the sufferer survived nearly three-quarters of an hour after the occurrence.—*Reese.*]

The following are the symptoms which denote an extravasation of blood in the thorax. The patient feels great oppression, and such uneasiness as will not let him long continue in one position. Unless he bend his body very much forwards, in which position the diaphragm is relaxed, and not so much dragged by the weight of the extravasated fluid, he feels great difficulty in standing or sitting up. When the thighs are bent, the patient can lie with tolerable ease on his back; he is also not averse to lying on the side on which the wound is situated; but he cannot place himself on the opposite side without feeling very acute pain in the situation of the mediastinum.

His respiration is short, frequent, and interrupted by sighs; his veins become empty; a cadaverous paleness spreads over his countenance; his extremities become cold; a viscid perspiration covers his neck and temples; his teeth chatter; his pulse becomes weak; and if, as most frequently happens, the lungs are wounded, he spits up frothy blood, and air issues from the wound.

Though one might suppose the above class of symptoms always attendant on a considerable effusion of blood in the thorax, this is not the case. Wounded persons have been known to die of such an extravasation whose respiration was tolerably free, and who did not complain of suffering more inconvenience in one posture than another. Sabatier says, that several facts of this kind have fallen under his own observation. Other wounded persons also, who suffered most of the complaints ascribable to extravasation of blood in the thorax, have been cured by ordinary means. Mery gives an account of a young man, wounded in the anterior and superior part of the chest, about two o'clock in the morning, who had such difficulty of breathing and fever five hours afterward, that an extravasation was supposed to exist, and Mery was thinking of making an opening for its evacuation. A tumour near the great pectoral muscle, presenting neither the feel of fluctuation, nor that of emphysema, made him suspend his decision. The tumour was dispersed by bleeding, and the application of compresses dipped in a mixture of spirit of wine and water.

However, even the assemblage of the above symptoms did not deceive Petit. Having been requested to assist at an operation which was about to be done on a wounded man, about whose armpit, pectoralis major, and latissimus dorsi muscles, a prodigious emphysematous swelling had taken place; whose respiration was painful and difficult; and who spit up frothy blood; Petit gave it as his opinion, that it was unnecessary to make an opening into the chest. He thought it would be sufficient to enlarge the wound, which was at a little distance from the armpit, near the edge of the latissimus dorsi, so as to give vent to the effused air. This advice was followed, the emphysema soon dispersed, and the patient recovered.

The equivocal nature of the symptoms of extravasations of blood in the thorax, has induced practitioners to pay the most scrupulous attention to every circumstance attendant on these cases. In several instances, Valentin remarked, that an ecchymosis occurred at the angle of the false ribs, and spread towards the loins. The ecchymosis is described as being of a clear purple colour, like the spots which sometimes form on the abdomen a little while after death. In a case, in which most of the symptoms of extravasation were combined with the above sort of ecchymosis, Valentin advised a counter-opening to be made. The advice was overruled and the patient soon afterward died: more than six pints of blood were found extravasated in the thorax.

Sabatier remarks, that we cannot too highly applaud the zeal of those practitioners who endeavour to dispel the doubts which still prevail in several parts of surgery. At the same time, he thinks that all who take interest in the improvement of this science should endeavour to ascertain the truth of any new observations which are offered. Hence, he deems it proper to relate a case which was communicated to him by M. Saucerotte (the father), an eminent military surgeon, and which shows, that the ecchymosis observed by Valentin is, at least, not invariably attendant on extravasations of blood in the chest. A light-horseman, who had received a thrust with a sabre in the right side of the thorax, above the tendon of the pectoralis major, appeared to be going on very well for the first four days after the accident. On the fifth, he complained of difficulty of breathing, uneasiness, and an inability of lying on the left side, without aggravating his complaints. He complained of a great deal of pain in the region of the liver, and at the top of the shoulder. His pulse was small and contracted, and rather hard than weak. The right side of the chest seemed larger than the left. On the eighth and ninth days the symptoms became more urgent, and the patient found no ease except in leaning on his right side, and supporting himself on a chair placed across his bed. This assemblage of symptoms indicated an extravasation of blood in the right cavity of the thorax; but as the ecchymosis which Valentin has described, was not apparent, doubts were entertained about the real nature of the case. When a counter-opening was made on the dead body, a pint of putrid blood flowed out.

When the surgeon feels assured that an extravasation of blood in the thorax has really occurred, and the symptoms are very urgent, the discharge of the confined fluid appears to promise benefit. However, before the operation is done, the revived state of the pulse, the return of warmth in the extremities, and the cessation of great faintness, ought to denote, that the hemorrhage no longer continues from the vessels; for, if this be not the case, a fresh quantity of blood must soon be extravasated again, and the patient die exhausted.

Authors mention five methods of discharging blood from the thorax; viz. 1st, By placing the patient in a posture which favours the escape of the blood; 2dly, By introducing a syringe for the purpose of sucking it out, or a mere cannula through which it is to flow; 3dly, By enlarging the wound; 4thly, By employing injections; 5thly, By making an opening in a depending part of the thorax.

1. Success cannot be expected from merely placing the patient in a posture which is favourable to the escape of the extravasated blood, except when the wound is situated at the inferior part of the chest, and is large and direct in its course. Paré successfully adopted this method in the case of a soldier, who was stabbed in three places with a sword, one of the wounds, which entered the chest, being situated under the right nipple. The man was first dressed by a surgeon, who made several sutures. The patient was soon afterward

attacked with considerable difficulty of breathing, fever, coughing, spitting of blood, and acute pain in the side. Paré, who was consulted the next day, suspected that an extravasation had happened; consequently he cut out the sutures, and placed the patient in a position in which his feet were much more raised than the head. Paré also recommended him to hold his breath, and then introduced his finger into the wound, in order to take away some clots of blood which appeared at its orifice. By these steps the discharge of seven or eight ounces of fetid, coagulated blood was effected.

2. The idea of drawing out of the thorax extravasated blood with a syringe, is rather ancient. The pipes of all syringes for this purpose should have blunt ends, lest they injure the lungs. Mere tubes, containing a stilet, have also been frequently employed. Scultetus relates a case, in which an instrument of the latter sort was successfully employed. No syringe or any suction with the mouth was requisite; it was found necessary merely to introduce the tube, and then withdraw the stilet.

Lamotte used only a simple cannula, which he introduced into the centre of the extravasation. Then having placed the patient in what he conceived to be the most favourable posture, and requested him to hold his breath, he drew off the collection of fluid. His cases, numbered 216, 217, 218, show the success which attended this method. Although it might also have answered very well in case 219, Lamotte saw that the high situation of the wound would not have allowed all the blood to be discharged, and therefore he made a counter-opening. Thus the thorax was completely emptied, and a recovery ensued. When a cannula is employed, authors recommend it to be introduced every day, till the bad symptoms cease and no more fluid escapes through the cavity of the instrument. After having given vent to blood, it allows a bloody serous fluid to escape, and at a later period pus, which becomes of a thicker and thicker consistence the nearer the patient is to a recovery.

3. The cases in which a wound, complicated with an extravasation in the chest, should be dilated, are those in which the situation of the opening is favourable to the escape of the blood. The operation is performed with a curved bistoury and a director. The integuments and external muscles are to be divided in a perpendicular direction, and the intercostal muscles in a line parallel to the ribs. Care is also to be taken not to cut too near the lower edge of the upper rib, lest the intercostal artery be wounded. Dionis practised such an operation on a soldier who was wounded at Befort, in 1703, with a sword, below the right nipple, whereby a direct opening was made into the thorax. When the extravasated fluid had been let out, Dionis made the patient lie on the wounded side during the night, and in proportion as the blood continued to be thus evacuated the breathing became free from oppression.

4. The methods above explained may be of use when the blood retains its natural state of fluidity; but when it is coagulated, as often happens, they can be of no avail. In this circumstance, most authors direct a proper opening to be made, and tepid water then to be thrown into the chest, with the view of loosening and dissolving the coagula and washing them out of the wound. The French writers, even the modern ones (*Sabatier*), most absurdly recommend the injection of various detergent vulnerary decoctions, and of solutions of honey of roses, soap, salt, &c. What idea these authors can entertain of the great tendency to inflammation of the lungs and pleura, or what good they can expect from such applications, is difficult of conception. I am firmly convinced, that the meanest scribbler on surgery, in this country, would be ashamed of offering such advice.

5. When the wound is narrow, and situated at the upper part of the chest, the extravasated blood cannot be discharged, unless a counter-opening be made at the lower part of this cavity. The best place for making the opening, and the proper manner of executing the operation, are described under the head of *Paracentesis*. As soon as the opening has been made, the blood flows out. Its discharge is then to be promoted by such a posture as will render the opening depending.

The old surgeons, who had much more fear than the moderns of letting the opening heal up, sometimes employed tents for the purpose of preventing this event, until all danger of another collection of blood or matter seemed to be over. However, as in these cases tents are apt to bring on inflammation of the pleura and lungs, hinder the escape of whatever fluid is contained in the chest, and cause great irritation, pain, and even exfoliations from the ribs, their use is now relinquished.

As large tents had the effect of hindering the discharge of blood or matter from the cavity of the chest, some of the old French surgeons employed a kind of wick; but in the present state of surgery, I do not consider that it would be at all edifying to enter into a comparison of these contrivances. If any means be ever requisite for keeping the opening from closing, there cannot be a better thing for the purpose than a short cannula, with a rim to keep it from slipping into the thorax, and two little rings for confining it in its situation with a riband. This should only just enter deeply enough to have its inner orifice on a level or a very little farther inwards than the pleura costalis, so that it may not irritate the lungs.

When the patient has been dressed, he is to be kept in bed, with his head and chest somewhat elevated, and his thighs bent, in which position the breathing will be least oppressed. It is usual also to recommend him to lie, as much as possible, on the side on which the operation has been done. He is to keep himself in as quiet a condition as he can. He is to be put on very low diet, and, if his strength allows, he is to be bled from the arm, and this evacuation must be repeated, with other antiphlogistic means, as often as the urgency of the fever and inflammatory symptoms indicate, and the strength allows. Bleeding from the arm, besides counteracting inflammation in the chest, which is a principal source of danger, does good by lessening the force of the circulation in the wounded vessels, and thus diminishing the tendency to internal hemorrhage.

The old practice of keeping wounds of the chest open is now nearly exploded; but if it ever be advisable, particular caution must be used not to let the tents and pieces of the dressings glide into the cavity of the pleura. Tulpius speaks of a Danish gentleman who had been under a careless surgeon on account of a wound in the thorax, and who coughed up, six months afterward, a large tent. A similar fact is recorded by Hildanus. A man was stabbed in the right side of the chest near the axilla, between the second and third ribs. For a fortnight, a great deal of blood was discharged both from the wound and the mouth. The wound healed; but the patient continued to be afflicted with considerable difficulty of breathing, an incessant cough, and to spit up a greenish fetid matter. Three months afterward he coughed up two tents which had slipped into the cavity of the thorax.

A relaxation of the antiphlogistic regimen must be made with very great circumspection. Too much nourishment, talking too frequently, and any exertion are circumstances which may induce a renewal of the hemorrhage and extravasation. Vesalius saw an accident of this nature happen a fortnight after the wound, and eleven days after the operation for empyema. A soldier, who had been stabbed in two places with a sword above the right nipple, was attacked with fever, difficulty of breathing, restlessness, and acute pain at the bottom of the chest. These symptoms induced Vesalius to infer, that an extravasation had taken place; but he was afraid of making an opening in the chest, for fear the hemorrhage should still continue from the wounded vessels. However, as the patient remained in the same state the fourth day after the receipt of the wounds, and he still had strength enough, Vesalius undertook the operation, by which a considerable quantity of extravasated blood was discharged. The patient felt great relief at the instant. The oozing of blood continued for a few days, after which a favourable suppuration took place in all the three wounds, and the case was expected to end well. But the patient having regained his strength and taken too much food, the recurrence of hemorrhage caused his death. Lombard saw a soldier die instantaneously of internal hemorrhage, brought on by throwing a bowl at some nine-pins, two months after he had been cured of a wound of the lungs.

When the edges of a penetrating wound of the chest are to be brought together, writers state, that the patient should be requested to make a strong inspiration.

with the wound closed, and then a long, slow expiration with it open, and so on, till as much of the air is discharged from the thorax as possible, and then the wound is to be accurately closed with sticking plaster. From what has been observed, however, in the article *Emphysema*, it will appear, that when there is a direct opening into the thorax, so as to admit the external air, the lungs on one side collapse, and remain so till the wound is healed and the air absorbed. When one of these organs is wounded, a collapsed state is, indeed, the best condition in which it can possibly be for a certain time, that is, till the breach of continuity in it is healed. Schemes for making the lung expand by exhausting the air from the cavity of the pleura may be amusing on paper, but, I apprehend, they will never be of real use in practice.

Fistulæ sometimes continue a long while after wounds of the thorax. Platner mentions an instance in which there was a fistulous opening, out of which the air rushed with sufficient force to blow out a candle. The patient lived a long while in this state without suffering any particular inconvenience.

Another occasional consequence of a wound of the chest is a hernia of the lungs, an affection of which Sabatier met with an example. A soldier, thirty years of age, was wounded with a bayonet in the right side of the chest, between the middle part of the fifth and sixth true ribs. The wound healed; but as the intercostal muscles had been divided to a great extent, and could not be approximated with precision, an empty space was left under the integuments, which allowed a piece of the lungs, as large as a walnut, to protrude between the ribs. The swelling enlarged at the time of inspiration, and grew smaller when expiration took place, occasioning merely a slight pain without any oppression in the chest.

Though so much has been written on the subject of discharging blood from the chest in cases of extravasation within that cavity, the operation is very rare. During the last thirty years, I have never heard of its being done by any of the surgeons in London. In military surgery, however, the practice is occasionally exemplified.—(*Larrey, Mém. de Chir. Mil. t.* 2, *p.* 158, *&c.*) No doubt, the true reason of the operation being uncommon is the obscurity in the diagnosis, the symptoms being all of an equivocal nature. Even Larrey, generally so partial to operations, recommends the immediate closure of all wounds of the chest, excepting such as are complicated with injury of the intercostal artery, because (says he), unless very considerable vessels of the lungs are injured (in which case nothing can be of any use), either no extravasation, or only a trivial one happens, which, under the employment of rigorous antiphlogistic treatment, may be dispersed by absorption.—(*P.* 127.) Respecting the general propriety of closing all wounds of the chest, I entirely concur with Larrey, Pelletan, Boyer, and Dr. Hennen. —(*On Military Surgery, ed.* 2, *p.* 373.)

Consult *Sabatier, De la Médecine Opératoire, t.* 2. *Journ. de Méd. Militaire, 7 tomes. Schmucker, Wahrnehmungen, 2 b. Berlin,* 1774—1789. *J. Bell, on the Nature and Cure of Wounds, ed.* 3. *D. J. Larrey, Mém. de Chir. Militaire, 8vo. Paris* 1812—1817, *in various places. John Hennen, Principles of Military Surgery, ed.* 2, *8vo. Edinb.* 1820. *Wm. Maiden, an Account of a Case of Recovery after an extraordinary Accident, 4to. Lond.* 1812. *The injury here referred to is one of the most extraordinary on record; the shaft of the gig having been driven with the greatest violence between the sternum and lungs. Sir A. Halliday, in Edinb. Med. and Surg. Journ. vol.* 11, *p.* 140; *a recovery from a gun-shot injury, in which a great part of the shoulder was carried away, and the lungs and pericardium were exposed: to the authenticity of this case I can bear witness myself, having been at the field hospital, when the soldier arrived from the trenches, near Antwerp.*

Wounds of the Abdomen.—Here one of the chief causes of danger is the tendency of the peritoneum to inflame. Every penetrating wound of the belly is apt to excite this inflammation, which too often extends itself over all the viscera, and terminates in the death of the patient.

There are (says Mr. John Bell) a thousand occasions on which the delicacy of the peritoneum may be observed. The wound of the small sword and the stab of the stiletto, explain to us how quickly the peritoneum and all its contained bowels inflame from the most minute wound, although the injury be almost too small to be visible on the outside and scarcely within; for often, upon dissection, no intestines are discovered wounded, and no feces have escaped into the abdomen. In subjects who die after lithotomy, we find the cavity of the peritoneum universally inflamed. The operation of the Cæsarean section is fatal, not from any loss of blood, for there is little bleeding; nor from the parts being exposed to the air, for patients also die in whom the womb bursts and where the air has no possible opportunity of insinuating itself; but the case proves fatal from the inflammation, which is always disposed to originate from wounds of the peritoneum, small as well as great.—(*Discourses on the Nature and Cure of Wounds, p.* 310, *edit.* 3.)

But although there can be no doubt that the wound, abstractedly considered, is the most frequent occasion of this dreadful inflammation; yet it sometimes happens that the inflammatory consequences must be ascribed to another kind of cause. If an intestine be wounded, its contents may, under certain circumstances, be effused in the abdomen; if the liver, spleen, kidney, or any large vessel be injured, blood may be poured out among the viscera; if the gall-bladder be wounded, bile may be effused; and if the bladder be pierced, the urine may escape into the abdomen. Now all these fluids are extraneous substances, with respect to the surfaces with which they often come into contact, and as such they give rise to inflammation of the peritoneum and viscera.

Wounds of the belly are divided, by almost all writers, into such as penetrate the cavity of the abdomen, and into others which only interest the skin and muscles.

The former differ very much in their nature and degree of danger, according as they do or do not injure parts of importance contained in the peritoneum. The latter are not remarkably different from the generality of other superficial wounds. The chief indications are to lower inflammation and to prevent collections of matter. A few particularities, however, in the treatment of superficial wounds of the abdomen merit attention.

Superficial Wounds.—The most ancient surgeons, and their successors down to the present day, have recorded, that wounds of tendinous parts frequently give rise to very unpleasant consequences. Almost the whole front of the abdomen is covered with tendinous expansions, and, on this account, it is not unusual to see punctured wounds in this situation followed by extensive inflammation and the formation of abscesses. At the same time, the patient is affected with a great deal of inflammatory fever. He suffers acute pain, sickness, hiccough, and considerable disturbance of the nervous system.—(*Callisen, Syst. Chirurg. Hodiernæ, vol.* 1, *p.* 698. *Hafniæ,* 1798.)

When the tension and swelling of the abdomen abate, shiverings sometimes occur, and indicate the occurrence of suppuration. The matter sometimes accumulates in the tendinous sheath of the rectus muscle, and when the collection in this situation remains undiscovered until a pointing appears, no sooner does the abscess burst, or it is opened, than an extraordinary quantity of matter is discharged. The surgeon should carefully remember the nature of this kind of case, as there is frequently not sufficient alteration in the appearance of the integuments to denote either the existence or the extent of the suppuration.

Such an abscess forms one remarkable exception to the excellent general rule of allowing acute phlegmonous abscesses to burst of their own accord. In the present instance, there is an aponeurotic expansion intervening between the abscess and the skin, and nothing retards the natural progress of the matter to the surface of the body so powerfully as the interposition of a tendinous fascia. But even in this circumstance the propensity of pus to make its way outwards is often seen to have immense influence. Though there is only a thin membrane (viz. the peritoneum) between matter so situated and the cavity of the abdomen, the abscess, after a time, mostly points externally.

The proper treatment of this case is to prevent the surprising accumulation of matter, and rapid increase of mischief, by making a depending opening, some-

times at the very lowest part of the sheath of the rectus muscle, and this, as soon as the lodgement of matter is clearly ascertained.

If ever there be a case in which it is advantageous and justifiable to make an early dilatation of a punctured wound, in order to prevent the above-described ill consequences, it is unquestionably the present one. Such practice, indeed, is particularly recommended by Callisen, in addition to the strictest antiphlogistic means.—(See *Syst. Chir. Hodiernæ*, *vol.* 1, *p.* 698, *edit.* 1798.)

Sometimes the matter is formed between the external and internal oblique muscles, and spreads to a great extent. The pus may even insinuate itself into the abdomen, and the case end fatally. Such an example is recorded by Dr. Crowther, of Wakefield. In this instance, however, the disease proceeded from a contusion, not a wound.—(See *Edinb. Med. and Surgical Journal*, *vol.* 2, *p.* 129.)

Superficial wounds of the abdomen are to be treated on the same principles as similar wounds in other situations. The indications are to prevent inflammation by all possible means, and if suppuration should be inevitable, to let out the matter by a depending opening as soon as the abscess is known to exist. The inflammation is to be checked by general and topical bleeding, low diet, emollient clysters, diluent beverages, quietude, opening medicines, cold applications or fomentations, and the mildest and most simple dressings.—(See *Inflammation*.)

Whenever the abdominal muscles are wounded, they should be relaxed, and the patient kept quiet in bed. A very important point in the treatment of wounds of the parietes of the abdomen, is to afford a degree of support to the wounded parts, so that the pressure of the viscera may be resisted. The sides of the abdomen are almost wholly composed of soft parts, which easily yield. No part of the front or sides of the abdomen is supported by a bony structure, and as the viscera are, for the most part, more or less moveable, and closely compressed by the abdominal muscles and diaphragm, they are liable to protrude whenever the resistance of the containing parts is not sufficiently powerful. Hence, all wounds of the abdomen, especially those in which both the integuments and muscles have been cut, demand strict attention to the precaution of supporting the wounded part, and this, though the peritoneum itself should not happen to be divided. The patient ought to keep as much as possible in a horizontal position, and suitable compresses and bandages should be applied. And, in order to guard against herniæ, the parts should be supported in this way a considerable time after the wound is healed.

The peritoneum being connected by means of cellular substance with the inner surface of the abdominal muscles there is always some risk of the inflammation of these parts extending to that membrane. The danger must be averted by the rigorous employment of antiphlogistic treatment. What renders the event still more dangerous is, that when one point of the peritoneum is affected, the inflammation usually spreads with immense rapidity over its whole extent, and too often proves fatal.

As superficial wounds of the abdomen are to be treated on the general principles applicable to all resembling wounds in other situations, it is hardly necessary to state, that union by the first intention, if possible, is always to be attempted.

Of Wounds penetrating the Cavity of the Abdomen.—The first thing which the surgeon is generally anxious to know, when he is called to a wound of the belly, is, whether the wound penetrates the cavity of the abdomen, and whether any of the viscera are injured.

When the wound is extensive, and the bowels protrude, the first part of the question is at once decided. But when the wound is narrow, and the viscera do not protrude, it is more difficult to know whether the cavity of the abdomen is penetrated or not. An opinion, however, may be formed, by carefully examining the wound with a finger or a probe; by observing, if possible, how much of the weapon is stained with blood; considering the direction in which it was pushed; the quantity of blood lost, the state of the pulse, and whether any bile, feces, or other fluids, known to be naturally contained in some of the abdominal viscera, have been discharged from the orifice of the injury.

When the wound is sufficiently large to admit the finger, a surgeon can always learn whether the injury extends into the abdomen, because the smooth lining of that cavity, and the contained bowels, may be easily felt. There is one chance of deception, however, arising from the possibility of mistaking the inside of the sheath of the rectus muscle for the cavity of the peritoneum; and when the examination is made with a probe, particular caution should be used in forming a judgment of the nature of the case; for the parts are so soft and yielding, that a very little force will make the instrument pass a considerable way inwards. Every examination of this kind should always be undertaken, if possible, when the patient is exactly in the same position in which he was at the time of receiving the wound. Formerly, injections were sometimes employed as tests of the penetration of the cavity of the abdomen. This absurd experiment is now very rightly exploded. It is well known to the moderns, that the space, termed the cavity of the abdomen, is in fact completely filled with the various viscera, and that in general, an injected fluid would not so easily find its way into the bag of the peritoneum, as an unreflecting person might suppose. And if it were propelled with much force, it would be quite as likely to insinuate itself into the cellular substance of the parietes of the abdomen or perhaps into the sheath of the rectus muscle. The least tortuosity of the wound, or a piece of bowel, or omentum, laying against the internal orifice of the injury, would also completely prevent an injection from passing into the abdomen.

When a considerable quantity of blood issues from a wound of the abdomen, we may pronounce, almost with certainty, that some large vessel within its cavity is injured. Excepting the epigastric artery, which runs on the forepart of the abdomen, along the inner surface of the rectus muscles, no large vessel is distributed to the muscles and integuments. At the same time, it is deserving of particular notice, that a large artery may be opened in the abdomen, and not a drop of blood be discharged from the wound.

In such cases, the consequent symptoms quickly lead to a suspicion of what has happened. The patient complains of extreme debility and faintness; his pulse falters; he has cold sweats; and if the bleeding should not speedily cease, these symptoms are soon followed by death.

Sometimes the extension of the wound into the cavity of the abdomen is from the first quite manifest, being indicated by the escape of chyle, bilious matter feces, or other fluids. The vomiting up of a considerable quantity of blood, or its discharge by stool, affords also the same information. The urine, however, may flow from a wound which does not actually penetrate the abdomen; for the kidneys, ureter, and bladder may be said to be out of the abdomen, because they are really outside of the cavity of the peritoneum.

When none of the above symptoms occur; when neither the finger nor the probe can be introduced; when none of the fluids known to be contained in the various receptacles in the abdomen are discharged from the wound; when the pulse remains natural, and the pain is not excessive, there is reason to hope that the wound has not injured parts of greater consequence than the integuments and muscles.—(*Encyclopédie Méthodique, partie Chir. art. Abdomen.*)

I have now taken a survey of the criteria commonly noticed by writers for the purpose of enabling surgeons to discriminate a wound which penetrates the abdomen from one which is more superficial. My next duty is to warn the practitioner, that too much solicitude to determine this point is very frequently productive of serious harm. It may be set down as an axiom in surgery, that *in general, whenever the probing of a wound is not rendered absolutely necessary by some particular object in view, it may be judiciously omitted.* A narrow oblique wound may enter the cavity of the abdomen without there being any particular method of ascertaining whether it has done so or not. However, this want of positive information is of no practical importance; for when there are no urgent symptoms evincing the nature of the case, the treatment ought obviously to resemble that of a simple wound; and whether the wound be deep or superficial, antiphlogistic remedies are indicated.

The edges of a wound penetrating the abdomen, but unattended with injury of the viscera, are to be brought together with sticking plaster, in the same way as com-

non wounds. Sutures are not generally necessary. Numerous cases may be found in the records of surgery, proving that wounds of the abdomen may be easily united without sutures, provided the surgeon take care to avail himself of the assistance which may be derived from a suitable position and a proper bandage. But such cases are less decisive than relations of the Cæsarean operation, the extensive wound of which admits of being healed by the same simple means. It is not my intention to assert, that in the majority of these examples, sutures were altogether dispensed with; but the ligatures frequently cut their way through the skin and muscles, and the application of others was impossible, either on account of the particular state of the case, or the patient's aversion to them. Still the union of such wounds was accomplished. A bandage made on the same plan as that with eighteen tails, would be extremely convenient for longitudinal wounds of the abdomen.—(See *Pibrac, in Mem. de l'Acad. de Chir. t.* 3, 4*to.*)

In the treatment of wounds of the abdomen sutures may generally be relinquished, not only without harm, but with benefit; for their employment is sometimes the cause of bad symptoms. In one instance, the hiccough and vomiting could not be appeased by any remedy which was tried. On the fourth day, the wound was inflamed and painful, and it was judged proper to cut away two sutures, and employ only simple dressings, with the view of diminishing the pain and swelling. The symptoms quickly abated, and in a week were entirely cured, the wound healing up very well. —(*Op. cit.*)

However, there are circumstances in which it would be impossible to dispense with sutures. If, for instance, the belly were torn open from one side to the other by a bullock's horn; or if it were extensively divided with the tusks of a wild boar, a stag's horn, a razor, &c., and the inflated intestines could not be kept from protruding, some stitches would be absolutely necessary; but even then, they should be as few as possible.—(*Sabatier, Médecine Opératoire, t.* 1, *p.* 214, *edit.* 2.)

"Our good old surgeon Wiseman (observes Mr. John Bell) has said with great simplicity, as a great many have said after him, 'it frequently happeneth, that a sword passeth through the body without wounding any considerable part.' He means that a rapier or ball often passes quite across the belly, in at the navel, and out at the back, and that without one bad sign the patient recovers, and, as has very often happened, walks abroad in good health, in eight days; which speedy cure has been supposed to imply a simple wound, in which all the bowels have escaped. But we see now, *how* this is to be explained; for we know that in a thrust across the abdomen, six turns of intestine may be wounded,—each wound may adhere; adhesion, we know, is begun in a few hours, and is perfected in a few days; and when it is perfect, all danger of inflammation is over; and when the danger of inflammation is over, the patient may walk abroad; so that we may do just as old Wiseman did in the case here alluded to (*P.* 98, the case of a man who was wounded across the belly, and well and abroad in seven days), 'bleed him, and advise him to keep his bed and be quiet.' In short, a man, thus wounded, if he be kept low, has his chance of escaping by an adhesion of the internal wounds?"—(*Discourses on the Nature and Cure of Wounds, p.* 329, 330, *edit.* 3.)

The truth of these observations is well illustrated in a case mentioned by Dr. Hennen, in which a soldier recovered, whose abdomen was pierced with a ramrod, which stuck so fast in the vertebræ, that some force was required to disengage it.—(*On Military Surgery, p.* 402, *ed.* 2.)

When a man is stabbed or shot in the belly, and none of the bowels protrude, the wisest plan is to keep the patient as quiet as possible, have recourse to copious and repeated bleeding, prescribe anodynes, and the lowest fluid diet, and apply light superficial unirritating dressings. In the event of severe pain and swelling of the belly coming on, leeches, fomentations, the warm bath, and emollient poultices will be necessary, and nothing will now avail except the most rigorous employment of antiphlogistic remedies. As Dr. Hennen observes, the best means of emptying the bowels are oleaginous clysters, and if any internal medicine be given as a purgative, it should be of the mildest nature. —(*On Military Surgery, p* 402, *ed.* 2.) Castor oil is perhaps the best; but, on the whole, for some few days I would hardly venture beyond the use of clysters for procuring evacuations from the bowels.

Suppuration in the Abdomen, in consequence of Wounds.—Abscesses within the bag of the peritoneum are far from being common. As a late writer well observes, the containing and contained parts of the abdomen present to each other a uniform and continuous surface of membrane. This membrane is of the serous class, and the species of inflammation to which it is especially subject is that which has been denominated the adhesive. The membrane lining the intestinal canal is of the mucous class, and the ulcerative inflammation is the species to which this class is liable. This beneficent provision is an irresistible evidence of the operation of a salutary principle in disease. If the inflamed peritoneum had run directly into suppuration, ulceration of surrounding parts would have been required for an outlet; and if the internal surface of the irritated bowel had tended to form adhesions, the canal would have been in constant danger of obliteration.—(*Travers on Injuries of the Intestines, &c. p.* 10.)

That collections of matter, however, do sometimes take place in the cavity of the abdomen, in consequence of wounds, is a fact of which there are too many proofs on record, for the possibility of the case to be doubted. At this moment, be it sufficient to refer to two examples of the occurrence, as related by Mr B. Bell.—(*System of Surgery, vol.* 5, *p.* 256.)

If the abscess were in any other part of the body and did not readily point, the wisest practice would undoubtedly be to make an opening sufficient for the evacuation of the matter. But suppuration in the abdomen can seldom be known with certainty in an early stage of the case; for the abscess is so deep, that no fluctuation nor swelling is perceptible, until the quantity of pus is considerable. Nor would it be judicious to expose the patient to the hazard which might arise from making an opening into the abdomen, merely for the sake of discharging a small quantity of matter.

Many writers impute much of the danger of wounds of the abdomen to the entrance of air into the cavity of the peritoneum. In inculcating such opinions, however, they betray an inaccuracy of observation, which a very little reflection would have set right. Too much stress has long been laid on the introduction of air into the abdomen, as being a cause of inflammation. The fact is, the cavity of the belly is always so completely occupied by the several viscera, that the whole inner surface of the peritoneum is invariably in close contact with them, and therefore air cannot easily diffuse itself from the wound, throughout the abdomen. After tapping, in dropsical cases, inflammation seldom arises, though here the air has quite as good an opportunity of entering the abdomen as in any case of wound. The peritoneum in animals has been inflated without any inflammation being excited. In cases of tympanitis, the peritoneum is distended with air, and yet both this membrane and the bowels are quite uninflamed. In the human subject, it seems probable, that if a wound were made in a vacuum, the breach of continuity itself would be an adequate cause of inflammation. It may also be remarked, that collections of matter in the abdomen are almost always completely circumscribed, and separated from the general cavity of the peritoneum, by the adhesion of the viscera to each other, and to the inside of the peritoneum.

I am of opinion, that no surgical writer has succeeded so well as Mr. John Bell in exposing the absurd apprehensions, not uncommonly entertained by practitioners, respecting the entrance of air into the abdomen and other cavities of the body. He inquires: 1st, Whether air can really get into the cavity of the abdomen? and, 2dly, Whether, if it were there, it would produce the dreadful effects ascribed to it?

Upon the first question, his arguments run thus:—"Suppose a wound of an inch in length:—suppose the bowel to have sunk, in some strange way, into the pelvis, for example, so as to have left a mere vacuum; what should happen with the flexible parietes of the abdomen? Should they stand rigid, while the air rushed into the cavity to fill it? No, surely. But, on the contrary, the walls of the abdomen would fall together, and the pressure of the outward air, far from making the air rush in by the outward wound, would

at once lay the belly flat and close the wound. But since the walls of the abdomen are not flaccid, nor the cavity empty, but the abdomen full, and the flat muscles which cover it acting strongly, the effect must be much more particular; for the moment that the belly is wounded, the action of the muscles would force out part of the bowels; the continuance of that action is necessary to respiration; the respiration continues as regular after the wound as before; and the continual pressure of the abdominal muscles and the diaphragm against all the viscera of the abdomen, prevents the access of air so effectually, that though we should hold such a wound open with our fingers, no air could pass into the abdomen, farther than to that piece of gut which is first touched with the finger, when we thrust it into the abdomen. Nothing is absolutely exposed to the air, except that piece of intestine which is without the abdomen, or that which we see when we expose a small piece of the bowels, by holding aside the lips of the wound. The pressing forward of that piece, and the protrusion of a portion of the gut, proportioned always to the size of the wound; the pressure from behind, keeping that piece protruded, so that it is with difficulty we can push it back with our finger; this incessant pressure in all directions is an absolute security against the access of air. The intestine comes out, not like water out of a bottle, the place of which must be supplied by air entering into the bottle, in proportion as the water comes out; but the gut is pushed down by the action of the muscular walls of the abdomen, and that action follows the intestine, and keeps it down, and prevents all access of the air, whether the gut continue thus protruding, or whether it be reduced; for if it be reduced, the walls of the abdomen yield, allowing it to be thrust back, but admitting no air. Those who want to know the effect of air, diffused within the cavity of the abdomen, must make other experiments than merely cutting open pigs' bellies;—they must give us a fair case, without this unnecessary wound. We will not allow them to say, when they cut open the belly of any creature with a long incision, that the inflammation arises from the air; much less shall we allow them to say, when they open the belly with a smaller incision, that by that little incision the air gets into the abdomen, and that all the bowels are exposed to the air."—(*Discourses on the Nature of Wounds*, p. 343. 384.)

In adverting to the question, whether air is so irritating to the cavities of the body as many have supposed, Mr. John Bell criticises with much spirit and success the opinions published on this subject, by Dr. A. Monro, in his account of the bursæ mucosæ, as the annexed quotations will show. "That the vulgar should believe the first superficial impression that strikes them, of air hurting a wound or sore, is by no means surprising; but it is not natural that men bred to philosophy should allow so strange an assertion as this without some kind of proof. That the air which we breathe, and which we feel upon the surface so bland and delightful, should have so opposite a relation to the internal parts, that it should there be a stimulus more acrid and more dangerous than the urine, is not to be believed upon slight grounds. I do affirm (says Mr. John Bell) that it remains to be proved, that this fluid, which seems so bland and pleasant to all our senses, and to the outward surface, is yet a horrible stimulus, when admitted, as a celebrated author grandly expresses it, 'into the deep recesses of our body.'"—(*Monro's Bursæ Mucosæ.*)

With how much reason Mr. John Bell objects, that this doctrine is unfounded, will be manifest to every man of any discernment or impartiality.

"The air, for instance, escapes from the lungs, in a fractured rib, and first goes abroad into the thorax; then into the cellular substance; then the emphysematous tumour appears; but often without any scarifications, with very little care and assistance on our part, the air is absorbed, the tumour disappears, and without inflammation of the chest, or any particular danger, the man gets well. Here then is the air, within the cavity of a shut sac, filling the thorax, and oppressing the lungs, without any dangerous inflammation ensuing.

That the air may be pushed under the cellular substance over all the body, without causing inflammation, is very plain from the more desperate cases of emphysema, where the patients, after living eight or ten days, have died, not from inflammation, but from oppression merely, the body being so crammed with air, that even the eyeballs have, upon dissection, been found as tense as blown bladders. We have also many ludicrous cases of this kind, which prove this to our perfect satisfaction. Soldiers and sailors sometimes touch the scrotum with a lancet, introduce a blow-pipe, and blow it up to an enormous size, imitating herniæ, by which they hope to escape from the service. The old story of a man who was so wicked as to make a hole in his child's head, and blow it up, that he might show the child in the streets of Paris for a monster, is well authenticated; and I have little doubt, that a fellow, who knew how to do this, would blow it up every morning, and squeeze it out when he put the child to bed at night. Some villanous butchers, having a grudge at a soldier, found him lying drunk under a hedge: they made a little hole in his neck, and blew him up till he was like a bladder, or, as Dr. Hunter describes the disease of emphysema, *like a stuffed skin.*"—(*P.* 388, 389.)

After many other pertinent observations, blended with appropriate satire on the extravagant notions professed by Monro, on the bad effects of the air, in lithotomy, operations for hernia and hydrocele, the Cæsarean section, &c., Mr. John Bell most justly holds up to ridicule the proposition of Dr. Aitken, *to perform this last operation under the cover of a warm bath, in order to exclude the air.* "This, though it may seem to be a scurvy piece of wit, was really proposed in sober serious earnest. But (adds Mr. John Bell) the admission of atmospheric air, as a stimulus, when compared with the great incisions of lithotomy, of hernia, of hydrocele, of Cæsarean section, of the trepan, is no more than the drop of the bucket to the waters of the ocean. And it is just as poor logic to say, that after such desperate operations, these cavities are inflamed by the admission of air, as it would be to say (as Monro did), that when a man is run through the pericardium with a red-hot poker, that the heart and pericardium are inflamed by the admission of the air."—(*P.* 347, *edit.* 3.)

Enough, I conceive, has been said to dispel all the idle fear and prejudices which have prevailed concerning the bad effects of the air in wounds of the abdomen, as well as several other cases. When so justly eminent a man as Dr. Alexander Monro, senior, was disturbed by such apprehensions, it is not wonderful that many a poor ordinary member of the profession should have been terrified nearly out of his wits upon the subject; and for quieting this alarm, and exposing its absurdities, I really think Mr. John Bell deserving of particular praise.

In general, in all cases of wounds of the abdomen, it is an excellent rule never to be officious about abscesses which may take place, nor to exhibit partiality to such experiments as have been devised for learning precisely what bowel is wounded. It is quite time enough to interfere when the urgency of the symptoms confirms any suspicions which may be entertained. A great deal of harm is frequently done by handling and disturbing the wounded parts more than is necessary, and it is well known, that wounds at first attended with alarming symptoms frequently have a favourable termination. Swords, balls, and other weapons sometimes pass completely through the body without the patient suffering afterward any threatening symptom, or indeed any effects which, abstractedly considered, would authorize the inference that the viscera had been at all injured. Severe inflammations may not end in suppuration, and when pus is formed it is sometimes absorbed again. Nothing then indicates the necessity for the discharge of purulent matter in the abdomen, unless the fluctuation and situation of the abscess be very distinct, and the quantity and pressure of the matter clearly productive of inconveniences. Under these circumstances, the surgeon should make a cautious puncture with a lancet.

Protrusion of the Viscera.—The omentum and small intestines are the parts most liable to protrusion; but in large wounds the great intestines, the stomach, and even the liver and spleen may project through the opening. The *general* symptoms indicating a protrusion of the parts are sufficiently obvious; but it deserves attention, that in fat subjects the adipose membrane may project from the wound, and put on somewhat of the appearance of omentum. The *spe-*

stal symptoms are to be collected from a knowledge of the natural situation of the parts, and reflecting what region of the abdomen is wounded.—(*Callisen, Syst. Chir. Hodiernæ, t.* 1, 702 *and* 703, *edit.* 1798.)

From penetrating wounds considerable portions of the bowels or omentum sometimes protrude; and though these viscera may not have received injury, yet their being displaced is sometimes productive of fatal consequences.

The best mode of preventing such mischief, is to return the viscera into the cavity of the abdomen as speedily as possible. Almost all authors recommend fomenting the displaced parts, previously to the attempt at reduction; but in giving this advice, they seem to forget, that while time is lost in this preparatory measure, the protruded bowels suffer much more harm from exposure, that is to say, from the very circumstance of their being out of their natural situation, than they can possibly receive good from any application made to them. No kind of fomentation can be half so beneficial as the natural warmth and moisture of the cavity of the abdomen. In order to facilitate the return of a protruded piece of intestine or omentum, the abdominal muscles should be relaxed by placing the patient in a suitable posture, and the large intestines emptied with a clyster. In mentioning the last measure, it is not meant, that the surgeon should delay the attempt to reduce the part until the clyster has operated. No, this means is only enumerated as one that may become serviceable in case the surgeon cannot immediately accomplish the object in view.—The mesentery ought always to be reduced before the intestine; the intestine before the omentum; but the last protruded portion of each of these parts ought to be the first reduced.

It is only when the intestine and omentum are free from gangrene and mortification, that they are invariably to be returned into the cavity of the belly without hesitation. Also, when the protruded parts are covered with sand, dust, or other extraneous matter, they should be tenderly washed with a little tepid water.

For the reduction of the parts, the fore-fingers are the most convenient, and it is a rule to keep the portion first returned from protruding again by one finger, until it has been followed by another portion introduced by the other finger. The second piece is to be kept up in the same way by the finger used to return it; and so on, till the displaced parts have all been put into their natural situation.

In attempting to reduce a piece of protruded intestine, the patient should be placed in the most favourable posture; the head and chest should be elevated, and the pelvis raised with pillows. Nothing can be more absurd than the advice to put the thorax rather lower than the pelvis, in order that the weight of the viscera may tend to draw inwards the protruded parts. This is another erroneous idea, arising from the ridiculous supposition, that a great part of the abdomen is actually an empty cavity. The relaxation of the abdominal muscles is a much more rational and useful object. When this is properly attended to, the above directions are observed, and the wound is not exceedingly small, in relation to the bulk of the protruded viscera, the parts may generally be reduced. But in addition to what has been already stated, it is necessary to remark, that the pressure should be made in a straight direction into the abdomen; for when made obliquely towards the edges of the wound, the parts are liable to suffer contusion without being reduced, and even to glide between the layers of the abdominal muscles, and become strangulated. When the wound is in the front of the abdomen, pressure made in this unskilful way may force the viscera into the sheath of the rectus muscle, and cause the same perilous symptoms as arise from an incarcerated hernia.—(See *Hernia.*)

When the reduction seems complete, the surgeon should assure himself of it, by introducing his finger into the cavity of the abdomen, so as to feel that the parts are all actually reduced, and suffer no constriction between the edges of the wound and the viscera in the abdomen.

A difficulty of reduction may arise from the protruded intestines being distended with feces or air. In this circumstance, the contents of the gut may frequently be made to pass by degrees into that portion of the intestinal canal which is within the abdomen. In order to accomplish this purpose, the surgeon must press the contents of the bowel towards the wound, and if he succeeds in emptying the part, he will commonly experience equal success in his next attempt to replace it in the abdomen.

Sometimes, in cases of narrow stabs, considerable pieces of intestine protrude, and cannot be reduced without doing imprudent violence to the bowel. Under these circumstances, the dilatation of the wound is indispensable. However, when the reduction seems almost a matter of impossibility, on account of the smallness of the wound, if the surgeon be careful to relax the abdominal muscles, draw a little more intestine out of the wound, and gently press the contents of the bowel through the constriction in the abdomen, he will frequently succeed in reducing the parts without using the knife.

When such operation is unavoidable, the dilatation should be made in a direction which will not endanger the epigastric artery, and, if possible, in the same line as the muscular fibres.

We are also advised to make the incision upwards rather than downwards, when it can be done with equal convenience, because it is supposed the first direction will be followed by less danger of hernia.—(*Sabatier, Médecine Opératoire, t.* 1, *p.* 220, *ed.* 2. *Callisen, Syst. Chir. Hod. t.* 1, *p.* 705.) If, however, the upper angle of the wound correspond to the direction of the suspensory ligament of the liver, writers advise making the dilatation at the lower angle, in order to incur no risk of hemorrhage from the umbilical vein. In the adult this vessel is generally obliterated, and turned into a ligamentous substance: though it would appear that, in a few instances, it remains pervious to the navel. Hildanus saw a young man die instantly in consequence of a stab in the belly between the false ribs and the umbilicus, and on opening the body, he found blood effused from a wound of the umbilical vein. It has been feared also, that cutting the suspensory ligament of the liver might give rise to such a displacement of that viscus as would interrupt the freedom of respiration, or obstruct the circulation of the blood in the vena cava. But the apprehension is unfounded; for Riolan found this ligament ruptured and retracted towards the liver in a nimble Æthiopian female dancer whose respiration had not suffered any particular disturbance during her lifetime.—(*Sabatier, Méd. Opératoire, t.* 1, *p.* 220, 221, *ed.* 2.)

The incision should never be larger than absolutely requisite, as hernia is much disposed to occur wherever the peritoneum has been divided. The operation may be done with a curved bistoury and a director, much in the same way as is done in cases of strangulated ruptures.—(See *Hernia.*)

After the battle of Waterloo many cases presented themselves in which the bowels and omentum protruded, and in several of these examples the reduction could not be effected before the wounds had been enlarged. So tightly also were the parts girt, that the operation was sometimes far from being easy.

Instead of enlarging wounds of the abdomen, it has been proposed to let out the air from the protruded intestines, by making small punctures with a needle, so as to lessen their volume sufficiently to make them reducible. The suggestion first originated with Paré, who declares, that he had practised the method with success. Rousset, his contemporary, also informs us, that the plan was adopted by another surgeon, in an instance where the epigastric region was wounded, and a large portion of the intestines protruded in a strangulated state. Peter Lowe, an English surgeon, likewise assures us, that he frequently adopted the practice when other means failed. Garengeot, Sharp, and Van Swieten are all advocates for Paré's proposal; but they recommend the employment of a round needle, which will merely separate the fibres of the intestinal canal without cutting them, as a flat, triangular, sharp-edged needle would unavoidably do. These last writers, however, only sanction the practice when the quantity of protruded intestine is great, and the bowel is so enormously distended with air, that it would be impossible to reduce the part, though the wound were enlarged, and every thing else put in practice likely to bring about the reduction. But, as Sabatier remarks, the punctures must be entirely useless, if made with a fine needle, since they will be im-

mediately stopped up with mucous secretion, with which the bowel is constantly covered; and if the punctures are made with a broad triangular needle, or a very large round one, as Desault and Chopart advise, they must be highly dangerous, inasmuch as they are likely to give rise to inflammation, and even to extravasation within the abdomen.—(*Médecine Opératoire, t.* 1, *p.* 10.)

That small punctures in the bowel would not answer the purpose, but be obstructed by the villous or mucous coat, is a fact which has been for a long time well known to surgeons. Callisen, among others, has particularly noticed it: "acu punctureæ enim flatibus exitum parare nequeunt, siquidem tunica villosa foraminula obstruit," &c.—(*Syst. Chir. Hod. t.* 2, *p.* 704.)

It was the circumstance of small punctures being unavailing, that led Desault and Chopart to recommend the use of a large round needle, "*pour que l'ouverture ne soit point bouchée par les mucosités dont les intestins sont enduits.*" But they were also aware of the danger of employing such an instrument, since they give us directions how to proceed, in order to prevent extravasation and inflammation: "*On préviendra l'épanchement des matières stercorales en passant, avant de réduire l'intestin, une anse de fil dans la portion de mésentère qui répond à la piqûre pour la fixer contre les bords de la plaie extérieure, et l'on combattra par les remèdes généraux l'inflammation que cet piqûre peut attirer.*"—(*Traité des Maladies Chirurg. t.* 2, *p.* 135.) Richerand is still an advocate for puncturing the bowel, for which operation he boldly recommends a small hydrocele trocar.—(*Nosogr. Clin. t.* 3, *p.* 336, *ed.* 4.)

Mr. Travers, one of the latest and best writers upon this subject, most properly joins in the condemnation of the plan of pricking the protruded bowels. "Blancard and others protested against this practice, on the very sufficient ground of its inefficacy. La Faye very truly says, it is a useless as well as dangerous practice; for the opening made by a round needle cannot give issue to the contained air." Mr. Travers then cites two cases, showing that even small stabs in a bowel will not prevent its becoming distended with air.

"A man was brought to St. Thomas's Hospital on Saturday, the 30th of June last (1811), who had been stabbed in the direction of the epigastric artery, on the left side of the abdomen, by a case-knife. He died in eighteen hours, apparently from the sudden and copious hemorrhage which had taken place within the belly. About half a yard of ileon was protruded. The gut was highly discoloured, and so much distended, notwithstanding it was pierced in three places, that the wound of the integuments required to be freely dilated before it could be returned. *The apertures were, in fact, obliterated by the mucous coat.*"

"It appeared upon the trial of Captain Sutherland (Ann. Reg. June, 1809) for the murder of his cabin-boy, that the intestines had been extensively protruded through a wound near the left groin, and had lain exposed for four or five hours; that the dirk had pierced through one fold of intestine, and entered another; that the wound of intestine was *half an inch* long; that the reduction could not be accomplished until the parietal wound was dilated; and that the intestine was then returned, and the integuments sewed up."—(*Travers, On Injuries of the Intestines, p.* 174. 176.)

With respect to this last case, however, I must observe, that it does not satisfactorily prove what the author intends, namely, *that the bowel was distended with air, though there was a wound in it half an inch long;* for the evidence does not inform us that the difficulty of reduction was owing to this cause. I have seen a very small portion of omentum protrude through a wound, and baffle all endeavours to reduce it for nearly an hour The first case adduced by Mr. Travers, however, is more explicit and interesting; and we are to infer from it, and the observations of Haller, Callisen, &c., that the punctures made in an intestine are not closed by mucus, as Sabatier and Desault have asserted, but by the mucous coat itself.

As the above expedient has been recommended by writers of some weight, I thought that the subject should not be passed over in silence, and without a caution to the reader never to put any confidence in the method. The plan does not facilitate the business of the operator; there is not even this solitary reason in favour of the practice; and though it may have answered when large needles were used, and some patients so treated may have recovered, every person who has the least knowledge of the animal economy will easily comprehend how even the smallest opening, made in parts so irritable and prone to inflammation as the bowels, must be attended with greater danger than would result from enlarging a wound of the skin and muscles. Besides, the air may frequently be pressed out of the intestine in a safer way, as I have already described.

A wound of the abdomen, attended with one of the most considerable protrusions of the viscera that I have ever read of, is recorded by Mr. Hague, surgeon at Ripon:—"August 30th, 1808 (says this gentleman), I went to Norton Mills, about four miles from hence, to see John Brown, æt. 12 years, who had received a wound in the abdomen from a pair of wool-shears. On my arrival, which was little more than an hour after the accident, I found the poor lad in a very distressing situation; the *great arch* of the stomach, and the *whole of the intestinal canal* (duodenum excepted) contained within the abdomen, having protruded through the wound. The incision was on the left side of the body, commencing at about two inches below the scrobiculis cordis, and extending in a straight line near four inches in length, distant from the navel two inches, and he was quite sensible, and had vomited so as to empty the stomach. Very little blood was lost. I immediately proceeded very carefully to examine the protruded viscera, none of which were wounded, and reduced them as quickly as possible, beginning with the stomach, and following the regular course of the intestines; in the latter portion of which I distinctly felt feces of rather firm consistence. He complained of some pain during the reduction, though not much, and expressed great relief when the parts were completely returned. I now desired an assistant to lay the palm of his hand over the wound, and make some pressure upon it; for I found that without this the parts would soon have protruded again by the action of respiration, which was oppressed and laborious. I brought the sides of the wound together by five sutures, beginning from above downwards, and passed the needle on each side, quite through the integuments with the peritoneum, &c. The wound was also dressed with adhesive plaster, and covered with a bandage."—(Vide *Edinburgh Medical and Surgical Journal, vol.* 5, *p.* 129, *&c.*)

This case is interesting; for notwithstanding so unlimited a protrusion of the viscera, and the circumstance of the parts being left unreduced for more than an hour, a recovery ensued, under the judicious employment of bleeding, purging, anodynes, &c.

In La Caserne de St. Elizabeth, at Brussels, after the battle of Waterloo, the number of protrusions of the viscera which fell under my notice was much more considerable than what I previously had any idea of ever meeting with. I well remember, in my own part of the hospital, two protrusions of a large portion of the stomach, three of the bladder, and ten or twelve of the mesentery, omentum, or intestines.

Whether a suture should be used when the protruded intestine is wounded, is a subject which will be noticed in considering wounds of the intestines.

Some of the exposed intestine may have mortified before the arrival of surgical assistance. In cases of wounds, this event is rare; but in those of strangulated herniæ, it is not uncommon. The treatment is explained in the article *Hernia.*

When the protruded intestine is in a state of inflammation, its immediate reduction is, beyond all dispute, the means most likely to set every thing right. Even when the inflammation is considerable, the timely reduction of the displaced part, and the employment of antiphlogistic means, will often prevent gangrenous mischief. The dull, brown, dark-red colour of the intestine may induce the practitioner to suppose, either that the part is already mortified, or must inevitably become so; and consequently, he may delay returning it into its natural situation. But notwithstanding this suspicious colour of the intestine, its firmness will evince that it is not in a state of gangrene. The ultimate recovery of a portion of intestine so circumstanced is always a matter of uncertainty; but the propriety of speedily replacing the part in its natural

situation is a thing most certain. "Partes egressæ sanæ (observes Callisen) citissime sunt reponendæ, neque obstat mutatio coloris nativi in rubrum subfuscum"—(*Syst. Chir. Hod. t.* 1, *p.* 703, *edit.* 1798.) In case the bowel mortify after its reduction, all hopes of the preservation of life are not to be abandoned; as I have noticed in the articles *Anus, artificial*, and *Hernia*, in which last part of the book, many things necessary to be known concerning the mode of reducing protruded omentum will also be found.

When a piece of intestine cannot be reduced, granulations and new skin sometimes grow over it, and a cure follows, as the experience of Callisen confirms.—(*Op. cit. p.* 706.)

The protruded viscera having been reduced, the next object is to retain them in the abdomen until the wound is completely healed. When the wound is small, this is a matter of no difficulty: for it is enough to put the patient in a position which will relax the fibres of the wounded muscles, while the edges of the wound are maintained in contact with sticking plaster, and supported by a compress and bandage. Costiveness is to be removed by the mildest purgatives, such as the oleum ricini, or by laxative clysters, which are still preferable. But in cases of extensive wounds, even when the treatment is conducted with all possible judgment, it is occasionally difficult, and even impossible, to hinder the protrusion of the bowels by common dressings and a bandage. In this circumstance, the edges of the wound must be sewed together.—(See *Gastro-raphe.*) In modern times, however, sutures are much more seldom employed than formerly; and in the above article, some remarks are offered, proving that the generality of wounds of the abdomen do not require the practice.

When the omentum protrudes, and is strangulated by the narrowness of the opening, it soon contracts adhesions to it, unless speedily reduced. Should such connexion be already formed when the surgeon is first consulted, we are advised to cut off the portion which exceeds the level of the integuments, and to leave the rest in the wound. The latter will block up the opening, and have the good effect of preventing hernia.—(*Richerand, Nosogr. Chir. t.* 3, *p.* 339, *edit.* 4.) When the protruded omentum is sound and free from adhesions, it ought to be reduced without delay. But when the protrusion is large, and there is reason to fear, from the vomiting and the pains shooting from the wound to the epigastric region, that the stomach is dragged, the displaced part must be made free, and, if sound, reduced. Should it be in a mortified state, the dead part must be previously cut away, and any vessels which bleed tied separately with a piece of fine thread or silk, both ends of which may either be cut off close to the knot, and the part then reduced; or one end of the silk may be left out of the wound, and the other cut away. Practitioners who apprehend ill effects from leaving within the abdomen so small a particle of extraneous matter as the little knot of fine thread, will prefer the last method, and withdraw the ligature altogether as soon as it becomes loose.

Extravasation in the Abdomen.—Wounds of the abdomen may be complicated with extravasations of blood, chyle, excrement, bile, or urine. None of these complications, however, are half so frequent as an inexperienced practitioner would apprehend. The employment of the phrase *cavity of the abdomen* has paved the way to much erroneous supposition upon this subject, and has induced many absurd notions, which even the sensible observations long ago published by J. L. Petit have scarcely yet dispelled.

As a modern writer has observed, "There is not truly any cavity in the human body, but all the hollow bowels are filled with their contents, all the cavities filled with their hollow bowels, and the whole is equally and fairly pressed. Thus, in the abdomen, all the viscera are moved by the diaphragm and the abdominal muscles upwards and downwards, with an equable continual pressure, which has no interval; and one would be apt to add, the intestines have no repose, being kept thus in continual motion; but though the action of the diaphragm and the reaction of the abdominal muscles are alternate, the pressure is continual; the motion which it produces is like that which the bowels have when we move forwards in walking, having a motion with respect to space, but none with regard to each other, or to the part of the belly which covers them. The whole mass of the bowels is alternately pressed, to use a coarse illustration, as if between two broad boards, which keep each turn of intestine in its right place, while the whole mass is regularly moved. When the bowels are forced down by the diaphragm, the abdominal muscles recede; when the bowels are pushed back again, it is the reaction of the abdominal muscles that forces them back and follows them. There is never an instant of interruption of this pressure; never a moment in which the bowels do not press against the peritoneum; nor is there the smallest reason to doubt that the same points in each are continually opposed. We see that the intestines do not move, or, at least, do not need to move, in performing their functions; for in hernia, where large turns of intestines are cut off by gangrene, the remaining part of the same intestines is closely fixed to the groin, and yet the bowels are easy and their functions regular. We find the bowels regular, when they lie out of the belly in hernia, as when a certain turn of intestine lies in the scrotum, or thigh, or in a hernia of the navel; and where yet they are so absolutely fixed, that the piece of intestine is marked by the straightness of the rings. We find a person, after a wound of the intestine, having free stools for many days; and what is it that prevents the feces from escaping, but merely this regular and universal pressure? We find a person, on the fourth or fifth day, with feces coming from the wound! a proof, surely, that the wound of the intestine is still opposite, or nearly opposite, to the external wound. We find the same patient recovering without one bad sign! What better proof than this could we desire, that none of the feces have exuded into the abdomen?

If, in a wound of the stomach, the food could get easily out by that wound, the stomach would unload itself that way, there would be no vomiting, the patient must die; but so regular and continual is this pressure, that the instant a man is wounded in the stomach he vomits; he continues vomiting for many days, while not one particle escapes into the cavity of the abdomen. The outward wound is commonly opposite to that of the stomach, and, by that passage, some part of the food comes out; but when any accident removes the inward wound of the stomach from the outward wound, the abdominal muscles press upon the stomach, and follow it so closely, that if there be not a mere laceration extremely wide, this pressure closes the hole, keeps the food in, enables the patient to vomit, and not a particle even of jellies or soups is ever lost, or goes out into the cavity of the belly.

How (proceeds Mr. J. Bell), without this universal and continual pressure, could the viscera be supported? Could its ligaments, as we call them, support the weight of the liver? Or what could support the weight of the stomach when filled? Could the mesentery or omentum support the intestines; or could its own ligaments, as we still name them, support the womb? How, without this uniform pressure, could these viscera fail to give way and burst? How could the circulation of the abdomen go on? How could the liver and spleen, so turgid as they are with blood, fail to burst? Or what possibly could support the loose veins and arteries of the abdomen, since many of them, e. g. the splenic vein, is (are) two feet in length, is (are) of the diameter of the thumb, and has (have) no other than the common pellucid and delicate coats of the veins? How could the viscera of the abdomen bear shocks and falls, if not supported by the universal pressure of surrounding parts? In short, the accident of hernia being forced out by any blow upon the belly, or by any sudden strain, explains to us how perfectly full the abdomen is, and how ill it is able to bear any pressure, even from its own muscles, without some point yielding, and some one of its bowels being thrown out. And the sickness and faintness which immediately follow the drawing off of the waters of a dropsy, explain to us what are the consequences of such pressure being even for a moment relaxed. But, perhaps, one of the strongest proofs is this, that the principle must be acknowledged, in order to explain what happens daily in wounds; for though in theory we should be inclined to make this distinction, that the hernia or abscess of the intestines will adhere and be safe, but that wounded intestines, not having time to adhere, will become flaccid, as we see them do in dissections, and so, falling away from the external wound,

will pour out their feces into the abdomen and prove fatal; though we should settle this as a fair and good distinction in the theory, we find that it will never answer in practice. Soldiers recover daily from the most desperate wounds; and the most likely reasons that we can assign for it are the fulness of the abdomen; the universal, equable, and gentle pressure; and the active disposition of the peritoneum, ready to inflame with the slightest touch. The wounded intestine is, by the universal pressure, kept close to the external wound, and the peritoneum and the intestine are equally inclined to adhere. In a few hours that adhesion is begun, which is to save the patient's life, and the lips of the wounded intestine are glued to the lips of the external wound. Thus is the side of the intestine united to the inner surface of the abdomen; and, though the gut casts out its feces while the wound is open; though it often casts them out more freely while the first inflammation lasts; yet the feces resume their regular course whenever the wound is disposed to close."—(*John Bell's Discourses on Wounds, p.* 323. 327, *ed.* 3.)

The foregoing extract, though drawn up in a careless style, contains such observations as are well calculated to make the reader understand, that the abdomen is in reality not a cavity, but a compact mass of containing and contained parts; that the close manner in which the various surfaces are constantly in contact most powerfully opposes extravasations; and that, in fact, it often entirely prevents them. The passage cited impresses us with the utility of that quick propensity to the adhesive inflammation which prevails throughout every peritoneal surface, and which not only often has the effect of permanently hindering effusion of the contents of the viscera, by agglutinating the parts together, but which, even when an extravasation has happened, beneficially confines the effused blood in one mass, and surrounds it with such adhesions of the parts to each other as are rapid in their formation and effectual for the purposes of limiting the extent of the effusion, and preventing the irritation of the extravasated matter from affecting the rest of the abdomen.

It is to Petit that surgeons are indebted for more correct modes of thinking upon the foregoing subject; and it is with great pleasure that I here refer to his valuable observations.—(See *Mém. de l'Acad. de Chir.*)

But notwithstanding the reciprocal pressure of the containing and contained parts against each other, and the useful effect of the quickly-arising adhesive inflammation, in all penetrating wounds of the belly, complicated with injuries of the viscera, we are not to suppose, that extravasation never happens; but only that it is much less frequent than has been commonly supposed. Mr. Travers, with much laudable industry, has endeavoured to trace, more minutely than any preceding writer, the particular circumstances under which effusions in the abdomen are likely or unlikely to happen. "It being admitted (says he) that there are cases in which effusion does take place, it is easy to conceive circumstances which must considerably influence this event. If, for example, the stomach and bowels be in a state of emptiness, the nausea which follows the injury will maintain that state. If the extent of the wound be considerable, the matter will more readily pass through the wound than along the canal. A wound of the same dimensions in the small and large intestines will more readily evacuate the former than the latter, because it bears a larger proportion to the caliber. Incised and punctured wounds admit of the adhesion of the cut edges or the eversion of the internal coat of the gut, so as to be in many instances actually obliterated; whereas, lacerated or ulcerated openings do not admit of these salutary processes. Again, in a transverse section of the bowel, contraction of the circular fibre closes the wound; whereas, in a longitudinal section, the contraction of this fibre enlarges it. Such (says Mr. Travers) are the circumstances which combined, in a greater or less degree, increase or diminish the tendency to effusion."—(*On Injuries of Intestines, &c. p.* 13, 14.)

After the details of some experiments and cases, the preceding author makes, among other conclusions, the following:

1. That effusion is not an ordinary consequence of penetrating wounds.

2. That if the gut be full and the wound extensive, the surrounding pressure is overcome by the natural action of the bowel tending to the expulsion of its contents.

3. That if food has not recently been taken, and the wound amounts to a division of the gut, or nearly so the eversion and contraction of the orifice of the tube prevent effusion.

4. That if the canal be empty at the time of the wound, no subsequent state of the bowel will cause effusion, because the supervening inflammation agglutinates the surrounding surfaces and forms a circumscribed sac: nor can effusion take place from a bowel at the moment full, provided it retain a certain portion of its cylinder entire, the wound not amounting nearly to a semi-division of the tube, for then the eversion and contraction are too partial to prevent an extravasation.

5. That when, however, air has escaped from the bowel, or blood has been extravasated in quantity within the abdomen at the time of the injury, the resistance made to effusion will be less effectual, although the parietal pressure is the same, as such fluids will yield more readily than the solids naturally in contact.—(*P.* 25, 26. 100.)

6. That though extravasation is not common in penetrating wounds, it follows more generally in cases where the bowel is ruptured by blows or falls upon the belly, while the integuments continue unwounded.—(*P.* 36.)

7. That when the bowels are perforated by ulceration, there is more tendency to effusion than in cases of wounds.—(*P.* 38, *&c.*)

Mr. Travers attempts to explain the reason of the greater tendency to effusion in cases of intestine burst by violence than in those of ulceration, "by the difference in the nature of the injury which the bowel sustains when perforated by a sword or bullet, as in one case, or burst or ulcerated, in the other. A rupture by concussion could only take place under a distended state of the bowel, a condition most favourable to effusion, and from the texture of the part, a rupture so produced would seldom be of limited extent. The process of ulceration, by which an aperture is formed, commences in the *internal* coat of the bowel, which has always incurred a more extensive lesion than the peritoneal covering. The puncture or cut is merely a solution of continuity in a point or line; the ulcerated wound is an actual loss of substance. The consequence of this difference is, that while the former, if small, is glued up by the effusion from the cut vessels, or, if large, is nearly obliterated by the full eversion of the villous coat, the latter is a permanent orifice."—(*P.* 46.)

How much Mr. Travers and Mr. John Bell differ in opinion upon these latter points, will appear from the following passage: after adverting to the adhesion, which takes place between the viscera and the peritoneum, under a variety of circumstances attending disease, Mr. John Bell observes, "This it is which makes the chief difference, in point of danger, between an ulcerated and a wounded intestine; for, in a wound, there is, as we should suppose, no time for adhesion, nothing to keep the parts in contact, no cause by which the adhesion might be produced. But in an ulcer there is a slow disease, tedious inflammation, adhesion first, and abscess and bursting afterward; sometimes a fistula remains discharging feces, and sometimes there is a perfect cure. If a nut-shell, a large coin, a bone, or any dangerous thing be swallowed, it stops in the stomach, causing swelling and dreadful pain: at last a hard, firm tumour appears, and then it suppurates, bursts, the bowel opens, the food is discharged at every meal, till the fistula gradually lessens and heals at last. But where the stomach is cut with a broad wound of a sabre, the blood from the wounded epiploic vessels, or the food itself, too often pours out into the abdomen, and the patient dies, &c."—(*Discourses on Wounds, p.* 321, *ed.* 3.) The author afterward proceeds to explain how, in cases of penetrating wounds, the compact state of the containing and contained parts, and the incessant and equable pressure which the viscera sustain, frequently hinder effusion.

Which of these gentlemen is most correct I cannot presume to determine; and whether Mr. Travers's cases are deviations from what is most common, can only be decided by a comparative examination of a greater number of facts. When the intestines ulcerate, and thus rid themselves of foreign bodies, the general tenor of the cases on record undoubtedly affords us

little reason to be apprehensive of extravasation. Yet, with respect to ulceration of the intestines from other causes, circumstances may be very different. And it is but justice to state, that Mr. Travers's opinions have received some confirmation from an interesting case, published by Dr. J. Crampton, of Dublin. It is an instance of rupture of the stomach, and fatal effusion of its contents into the cavity of the abdomen. The patient was a young lady, aged 29. She was suddenly taken ill with spasm in her stomach, and other severe symptoms, and died in about twelve hours. "On opening the abdomen, the stomach was observed to be pale, flaccid, and empty. Its contents, among which were recognised oatmeal and castor-oil, had escaped into the cavity of the abdomen through a round aperture situated on its anterior surface at the union of the cardiac and pyloric portions. This perforation of the stomach was perfectly circular, about the size of a pea, and appeared to be the result of an ulcer on the mucous surface, which had gradually penetrated the other coats. This ulcer was hollow and circular, nearly the size of a shilling, and had the appearance as if it had been made with caustic, with the orifice in its centre." —(*J. Crampton, Med. Chir. Trans. vol.* 8, *p.* 230.) To the preceding, Mr. Travers has annexed some additional facts: one is an example of a rapidly fatal effusion of the intestinal contents through an ulcerated opening about a finger's breadth below the pylorus. The foramen had a peritoneal margin, and proved to be the centre of an irregular superficial ulcer of the mucous coat. Another case is that of a similar ulceration of the small intestines, and fatal extravasation of their contents. In another example, a circular aperture of the peritoneum, large enough to admit a crow's quill, was found after death at the junction of the duodenum and stomach. It also was the centre of an ulcer that had destroyed the villous and muscular coats of the bowel to the extent of half an inch. For many other ingenious observations, I must refer the reader to Mr. Travers's paper, who concludes with remarking, that the chief diagnostic symptoms of these hopeless cases appear to be:

1. Sudden, most acute, and unremitting pain, radiating from the scrobiculus cordis or the navel, to the circumference of the trunk, and even to the limbs. A peculiar pain, the intensity of which, like that of parturition, absorbs the whole mind of the patient, who, within an hour from the enjoyment of perfect health, expresses his serious and decided conviction, that if the pain be not speedily alleviated he must die.

2. Coeval with the attack of pain, remarkable rigidity and hardness of the belly, from a fixed and spastic contraction of the abdominal muscles.

3. A natural pulse for some hours, until the symptoms are merged in those of acute peritonitis and its fatal termination in the adhesive stage.—(*Med. Chir. Trans. vol.* 8, *p.* 231, *et seq.*)

Blood is more frequently extravasated in the abdomen than any other fluid, but it does not always take place, unless the wounded vessels be above a certain magnitude. The compact state of the abdominal viscera in regard to each other and their action on each other, oppose this effect. The action alluded to, which depends on the abdominal muscles and diaphragm, is rendered very manifest by what happens, in consequence of operations for herniæ, attended with alteration of the intestines or omentum. If these viscera burst or suppurate, after being reduced, the matter which escapes from them or the pus which they secrete is not lost in the abdomen; but is propelled towards the wound in the skin, and there makes its exit. The intestinal matter effused from a mortified bowel has been known to remain lodged the whole interval, between one time of dressing the wound and another, in consequence of the surgeon stopping up the external wound with a large tent. When the above-mentioned action or pressure of the muscles is not sufficient to keep the blood from making its escape from the vessels, still it may hinder it from becoming diffused among the convolutions of the viscera, and thus the extravasation is confined in one mass. The blood effused and accumulated in this way, is commonly lodged at the inferior and anterior part of the abdomen, above the lateral part of the pubes, and by the side of one of the recti muscles. The weight of the blood may propel it into this situation, or perhaps there may be less resistance in this direction than in others. In opening the bodies of persons who have died with such extravasations, things may put on a different aspect, and the blood seem to be promiscuously extravasated over every part of the abdomen. But when such bodies are examined with care, it will be found that the blood does not insinuate itself among the viscera till the moment when the abdomen is opened, and the mass previously lies in a kind of pouch. This pouch is frequently circumscribed and bounded by thick membranes, especially when the extravasation has been of some standing.—(*Sabatier, Médecine Opératoire, t.* 1, *p.* 28—30.)

Every practical surgeon should remember well, that all the abdominal viscera closely touch either each other or the inner surface of the peritoneum. This is one grand reason why extravasations are seldom extensively diffused; but commonly lie in one mass, as Petit, Sabatier, and all the best moderns have noticed. The pressure of the elastic bowels, diaphragm, and abdominal muscles, not only frequently presents an obstacle to the diffusion of extravasated matter, but often serves to propel it towards the mouth of the wound. The records of surgery furnish numerous instances in which persons have been stabbed through the body, without fatal consequences, and sometimes without the symptoms being even severe. In Mr. Travers's publication many cases exemplifying this observation are quoted from a variety of sources: *Fab. Hildan. Obs. Chirurg. cent.* 5, *obs.* 74. *Œuvres de Paré, liv.* 10, *chap.* 35. *Wiseman's Surgery, p.* 371. *La Motte's Traité Complet de Chirurgie, &c. &c.* In such cases the bowels have been supposed to have eluded the point of the weapon, and perhaps in a few instances this may actually have been the fact; but in the generality of such examples, the bowels must have been punctured, and the extravasation of intestinal matter prevented by the pressure of the viscera against each other.

The pouch or cyst in which the extravasated blood or matter lies, as mentioned by Sabatier, is formed by the same process which circumscribes the matter of abscesses.—(See *Suppuration.*) It is, in short, the adhesive inflammation. All the surfaces in contact with each other, and surrounding the extravasation and track of the wound, generally soon become so intimately connected together by the adhesive inflammation, that the place in which the extravasation is lodged, is a cavity entirely destitute of all communication with the cavity of the peritoneum. The track of the wound leads to the seat of the effused fluid, but has no distinct opening into the general cavity of the abdomen. The rapidity with which the above adhesions frequently form is almost incredible.

It should be known, however, that extravasations are occasionally diffused in various degrees among the viscera, owing to the patient being subjected to a great deal of motion or affected with violent spasmodic contractions of the intestines. Urine and bile are also generally dispersed to a great extent. As for blood, its disposition to coagulate must often tend both to stop farther hemorrhage and confine the extravasation in one mass.

Symptoms and Treatment of Extravasations in the Abdomen. 1. *Blood.*—Wounds of the spleen and of very large veins and arteries in the abdomen, almost always soon prove fatal from internal hemorrhage. The blood generally makes its way downwards, and accumulates at the inferior part of the abdomen, unless the presence of adhesions happen to oppose the descent of the fluid to the most depending situation. The belly swells, and a fluctuation is perceptible. The patient grows pale, loses his strength, is affected with syncope, and his pulse becomes weak and is scarcely distinguishable. In short, the symptoms usually attendant on profuse hemorrhage are observable. As the viscera and vessels in the abdomen are compressed on all sides by the surrounding parts, the blood cannot be effused without overcoming a certain degree of resistance; and unless a vessel of the first magnitude, like the aorta, the vena cava, or one of their principal branches has been wounded, the blood escapes from the vessel slowly, and several days elapse before any considerable quantity accumulates.

In these cases, the symptoms which, perhaps, had disappeared under the employment of bleeding and anodyne medicines, now recur. A soft fluctuating tumour may be felt at the lower part of the abdomen

sometimes on the right side; sometimes on the left; but occasionally on both sides. The pressure made by the effused blood on the urinary bladder, excites distressing inclinations to make water; while the pressure which the sigmoid flexure of the colon suffers is the cause of obstinate constipation. In the mean time, as the quantity of extravasated blood increases, the peritoneum inflames. The pulse grows weaker, debility ensues; the countenance becomes moistened with cold perspirations; and according to some writers, unless the surgeon practise an incision for the discharge of the fluid, the patient falls a victim to the accident.

In the year 1733, Vacher adopted this treatment with success. Petit afterward tried the same plan, though it did not answer (as is alleged) in consequence of the inflammation having advanced too far before the operation was performed. Long before the time of Vacher and Petit, a successful instance of similar practice was recorded by Cabrole, in a work which this author published under the title of Ἀλφαβῆτον ἀνατομικὸν, id est, Anatomes Elenchus accuratissimus, omnes humani Corporis Partes ea quâ solent secari Methodo, delineans. Accessere Osteologia, Observationesque Medicis ac Chirurgicis perutiles, Genevæ, 1604. The method pursued by Vacher was therefore not so new as Petit imagined.

Indeed, when the symptoms leave no doubt of there being a large quantity of blood extravasated in the abdomen; when the patient's complaints are of a very serious nature, and are evidently owing to the irritation and pressure of the blood on the surrounding viscera; and when a local swelling denotes the seat of the extravasation, there cannot be two opinions about the propriety of making an incision for its evacuation.

Surgeons should recollect, however, that if no opening be made, a small extravasation of blood may not produce any considerable irritation. On the contrary, when the cyst including the blood is opened, the air then has access, and that part of the fluid which cannot be discharged putrefies, and becomes so irritating as to be a true cause of inflammation. The bad symptoms are also sometimes chiefly owing to the injury done to parts within the abdomen, and still more commonly to inflammation within that cavity, arising rather from the wound than from the presence of effused blood. On the whole, I am disposed to join a late writer in the belief, that the practice of discharging extravasated blood from the abdomen can rarely be advisable.—(See *Hennen's Mil. Surgery*, *p.* 412, *ed.* 2.)

2. *Chyle and Feces.*—These are not so easily extravasated in the abdomen as blood, because they do not require so much resistance on the outside of the stomach and intestines to make them continue their natural route through the alimentary canal, as blood requires to keep it in the vessels. However, when the wound is large, and the bowel distended at the moment of the injury, or when, as Mr. Travers has explained, air is extravasated or blood effused in the abdomen, which fluids are incapable of making effectual resistance to the escape of the intestinal matter, the latter may be effused.—(See *An Inquiry into the Process of Nature in repairing Injuries of the Intestines, &c. p.* 26.) Nothing is a better proof of the difficulty with which chyle and feces are extravasated, than the operation of an emetic, when the stomach is wounded and full of aliment. In this instance, if the resistance to the extravasation of the contents of the stomach were not considerable, they would be effused in the abdomen instead of being vomited up. A peculiarity in wounds of the stomach and intestines is, that the opening which allows their contents to escape, may also allow them to return into the wounded viscus.

Extravasation of intestinal matter in the abdomen is attended with severe febrile symptoms; considerable pain and swelling of the belly; convulsive startings; and hiccough and vomiting, with which the patients are generally attacked the day after the receipt of the wound.—(*Sabatier, Méd. Opératoire, t.* 1, *p.* 34.)

In these cases, only general means can be employed; venesection, leeches, fomentations, low diet, perfect rest, anodynes, &c. All solid food must be strictly prohibited. If pressure can be borne without inconvenience, as is sometimes the case in the early stage, the close state of the viscera may be increased by the application of a bandage round the body.

If the symptoms are not speedily assuaged, the inflammation spreads over the whole cavity of the abdomen, gangrenous mischief takes place, and the patients die in the course of a few days.

3. *Bile.*—Bile, on account of its great fluidity, is more apt to be widely extravasated in the abdomen than either blood or the contents of the stomach and intestines. However, on account of the small size of the gall-bladder, and its deep guarded situation, between the concave surface of the liver and upper part of the transverse arch of the colon, wounds of it are uncommon.

Sabatier informs us, that he has only been able to find one example on record. This case was communicated to the Royal Society of London, by Dr. Stewart.—(*No.* 414, *p.* 341. *Abridgm. vol.* 7, *p.* 571, 572.) A wound penetrated the cavity of the abdomen, and entered the fundus of the gall-bladder, without doing any material injury to the adjacent parts. The abdomen was immediately distended, as if the patient had been afflicted with an ascites, or tympanitis; nor did the swelling either increase or diminish, till the patient's death, which happened in a week.

Though there was a great deal of tension, there was no rumbling noise in the abdomen. No stools and very little urine were discharged, notwithstanding purgatives and clysters and a good deal of liquid nourishment were given. Anodynes failed to procure one instant of sound sleep, and the patient was incessantly in a most restless state. There was no appearance of fever, and the pulse was always natural till the last day of the patient's life, when it became intermittent. After death, the intestines were found much distended, the gall-bladder quite empty, and a large quantity of bile extravasated.

Sabatier had an opportunity of noticing the symptoms of an extravasation of bile, in consequence of a wound of the gall-bladder. The patient's abdomen swelled very quickly, his respiration became difficult, and he soon afterward complained of tension and pain in the right hypochondrium. His pulse was small, frequent, and contracted; his extremities were cold, and his countenance very pale. The bleedings which were practised the first day gave him a little relief; but the tension of the abdomen and the difficulty of breathing still continued. A third bleeding threw the patient into the lowest state of weakness, and he vomited up a greenish matter. On the third day, the lower part of the belly was observed to be more prominent, and there was no doubt of an extravasation. Sabatier introduced a trocar, and gave vent to a green, blackish fluid, which had no smell, and was pure bile, that had escaped from the wound of the gall-bladder. After the operation, the patient grew weaker and weaker, and died in a few hours. On opening the body, a large quantity of yellow bile was found between the peritoneum and intestines; but it had not insinuated itself among the convolutions of the viscera. A thick gluten connected the bowels together, and they were prodigiously distended. The gall-bladder was shrivelled, and almost empty. Towards its fundus, there was a wound about a line and a half long, corresponding to a similar wound in the peritoneum. The wound which had occurred at the middle and lower part of the right hypochondrium, between the third and fourth false ribs, had glided from behind forwards, and from above downwards, between the cartilages of the ribs, until it reached the fundus of the gall-bladder.

Sabatier takes notice that the symptoms of the two cases, which have just now been related, were very similar. Both the patients were affected with an exceedingly tense swelling of the belly, unattended with pain or borborygmus, and they were both obstinately constipated. Their pulse was extremely weak the latter days of their indisposition, and they were afflicted with hiccough, nausea, and vomiting.

Sabatier seems to think one thing certain, viz. that wounds of the gall-bladder, attended with effusion of bile, are absolutely mortal, and that no operation can be of any avail.—(*Médecine Opératoire, t.* 1, *p.* 34—37.)

A contrary inference, however, may be drawn from a case detailed by Paroisse, in which a bullet had lodged in the gall-bladder two years.—(*Opuscules de Chir. p.* 255.) The recovery published by Mr. Fryer, of Stamford, tends also to prove that every effusion of bile is not unavoidably fatal. A boy, about thirteen years old, received a violent blow from one of the

shafts of a cart, on the region of the liver. The injury was succeeded by pain, frequent vomiting of bilious matter, great sinking, coldness of the extremities, and a weak, small, fluttering pulse. The belly was fomented, and purging clysters thrown up. On the third day, symptoms of inflammation began, attended with considerable pain about the liver, great tension and soreness of the abdomen, and frequent vomiting. The pulse was quick, small, and weak; the skin hot and dry; the tongue much furred; the urine high-coloured; and there was some difficulty of breathing, and great thirst. Eight ounces of blood were taken away, the fomentations continued, and a few grains of calomel were directed to be given every four hours, until the bowels were properly opened. Afterward, the effervescing mixture, with ten drops of laudanum, was exhibited every four hours.

On the following day the patient had some motions, and was much better; but, as his sickness continued, he was ordered a grain of opium every four hours. About a week afterward, he complained of a great increase of pain, which was somewhat relieved by a blister. He was now completely jaundiced, and his stools were white, but the tension, pain, and sickness were abated.

Two days afterward, a fluctuation was perceived in the abdomen, which, in another week, became considerably distended with fluid. The patient now did not complain of much pain, but appeared to be sinking fast; a puncture was made in the swelling, and thirteen pints of what appeared to be pure bile were evacuated. The bowels then soon became regular, and the appetite good. In twelve days, the operation was repeated, and fifteen pints of the same bilious fluid were drawn off. Nine days afterward, another puncture was made, and thirteen pints more let out: and six were discharged in another fortnight. From this period the boy went on well, and perfectly recovered under the use of light tonic medicines.—(See *Med. Chir. Trans. vol.* 5, *p.* 330.)

A previous accidental adhesion of the gall-bladder to the peritoneum might also prevent the extravasation of bile and its dangerous effects.—(*Callisen, Syst. Chir. Hodiernæ, t.* 1, *p.* 718.)

According to Dr. Hennen, a deep wound of the liver is as fatal as if the heart itself was engaged. The slighter injuries are recoverable. He states that the usual symptoms of a wound of the liver are yellowness of the skin and urine, derangement of the alimentary canal, and great and distressing itching of the skin. The discharge from the wound is generally yellow and glutinous, though sometimes either serous, or like unmixed bile.—(*On Military Surgery, ed.* 2, *p.* 429.) For some other interesting observations on wounds of the liver, I have great pleasure in referring to the latter work.—(See also *Wedekind de Vulnere Hepatis curato, Jenæ*, 1735; and *Thomson's Report of Obs. made in the Military Hospitals in Belgium*, 8*vo*. 1816.)

4. *Urine.*—Urine being of a very fluid nature, may, like the bile, be extensively diffused in the abdomen, when the bladder is wounded at any part connected with the peritoneum. If in this kind of case the urine be not drawn off with a catheter, so as to prevent its extravasation, the patient soon perishes. Many instances are recorded of the bladder being injured even by gun-shot wounds, which were not mortal.

Wounds of the bladder are attended with a discharge of bloody urine and difficulty of making water. They are always dangerous cases, both on account of the risk of the effusion of so irritating a fluid in the abdomen, and of the chance of extravasation in the cellular membrane. Under proper treatment, however, they often admit of cure.—(See *Gun-shot Wounds.*) If possible, the effused fluid should be discharged by a depending posture, or suitable punctures, or incisions, and the recurrence of extravasation prevented by the introduction of a catheter, which is to be left in the urethra. The patient must also be allowed little drink. As for the tension and pain of the belly, the common attendants of a wounded bladder, they may be greatly relieved by the use of the warm bath (*Callisen, t.* 1, *p.* 719), or rather fomentations, which would not require the patient to be moved; bleeding, low diet, and other antiphlogistic means, not being omitted.

Wounds of the Stomach.—As Dr. Hennen has observed, these cases are extremely dangerous, though not always mortal. "Baron Percy calculates, that of twenty cases, four or five only have escaped; this, however, is a most favourable average." Two cures of the wounds of the stomach are reported by Dr. Thomson.—(*Obs. made in the Military Hospitals in Belgium, &c.*) With respect to the chances of recovery, Dr. Hennen justly remarks, that the histories of the Bohemian, Prussian (*D. Beckher de Cultrivoro Prussiaco*, 12*mo. Lugd.* 1638), and English "Cultrivores," in some of whom the knives have been cut out, and in others discharged spontaneously through the coats of the stomach and parietes of the abdomen, are very encouraging. In France, a silver fork was lately extracted from a young man's stomach, by Mr. Renaud, of Romans, in the department of the Drôme, who performed gastrotomy for the purpose with complete success.—(See *Quarterly Journ. of For. Med. No.* 18, *p.* 301.) Hevin has collected many instances of recovery, both from incised and gun-shot wounds of the stomach.—(*Mém. de l'Acad. de Chir. t.* 1.) But according to Dr. Hennen, Ploucquet, in the articles "Ventriculus" and "Pantophagi," has brought together the largest number of cases. Dr. Hennen also refers to *Lowthorpe's Abridgment of the Phil. Trans. vol.* 6, *p.* 192, for instances, in which the stomach of a horse was wounded and sewed up, and the same practice extended to the human subject with success. It appears, also, from the *Annales de Littérature, &c. t.* 2, by Kluyskens, from Schlichting's *Traumatologia*, and the *Bulletin de la Faculté, &c. t.* 5, *p.* 386, that wounds of the human stomach have been stitched with success, in various cases of recent date.—(See *Hennen's Military Surgery, ed.* 2, *p.* 438.) As the latter author observes, wounds of the stomach not unfrequently become fistulous, and remain open. In a case recorded by Richerand, the fistula continued open nine years; and in another instance, related by Ettmuller, ten years.—(*De Vulnere Ventriculi Programma, Lip.* 1730.) And Wencker has detailed a case, in which the opening continued twenty-seven years.—(See *Halleri Dissert. Chir. vol.* 5, *art.* 19.) For farther information connected with this subject, the reader may also consult *Jungen de Lethalitate Vulnerum Ventriculi, Helmst.* 1751; and *Ludov. Horn. de Ventriculi Ruptura*, 8*vo. Berol.* 1817. Also, *Med. Chir. Journ. vol.* 5, *p.* 72.

Wounds of the Intestines.—The vomiting of blood, or discharge of it by stool; the escape of fetid air or of intestinal matter from the mouth of the wound; an empty, collapsed state of a portion of bowel, protruded at the opening in the skin, are the common symptoms attending a wound of this kind. When the wound is situated in the protruded portion, it is obvious to the surgeon's eye; but when it affects a part of the intestinal canal within the abdomen, the nature of the case can be known only by a consideration of other symptoms. In addition to such as I have already described, there are some others which ordinarily accompany wounds of the bowels; as, for instance, oppression about the precordia, acute or griping pain in the belly, cold sweats, syncope, &c. But unless the wounded intestine protrude, there is no practical good in knowing whether the bowel is injured or not; since, if it be in the abdomen, the treatment ought not to be materially different from that of a simple penetrating wound of the belly, unattended with a wound of any of the viscera. Large wounds of the small intestines, particularly of the duodenum and jejunum, are attended with acute fever, anxiety, paleness of the countenance, syncope, cold perspirations, a small, intermitting, tremulous pulse, and they frequently prove fatal. Injuries of the small intestines are also more often than those of the large ones followed by extravasation. A total division of the upper part of the intestinal canal, towards the pylorus, will deprive the body of the nourishment requisite for its support. If the chyle escape from the wound, the patient will die of a slow marasmus; and if it become extravasated, it will be likely to excite such irritation as will prove fatal. The escape of excrement or of fetid air from the wound, indicates an injury of one of the large intestines. In these cases, the symptoms are generally milder, and the passage of the intestinal contents outwards, through the wound, more easy, on account of the bowel being less moveable. For the same reason, the wounded intestine more readily contracts an adhesion to the adjacent

parts.—(*Callisen, Syst. Chirurgiæ Hodiernæ, t.* 1, *p.* 717.)

A wounded intestine is said to present some particular appearances, to which the generality of writers have paid no attention: "If a gut be punctured, the elasticity of the peritoneum, and the contraction of the muscular fibres, open the wound, and the villous or mucous coat forms a sort of hernial protrusion and obliterates the aperture If an incised wound be made, the edges are drawn asunder, and averted so that the mucous coat is elevated in the form of a fleshy lip. If the section be transverse, the lip is broad and bulbous, and acquires tumefaction and redness from the contraction of the circular fibres behind it, which produces, relatively to the everted portion, the appearance of a cervix. If the incision be according to the length of the cylinder, the lip is narrow, and the contraction of the adjacent longitudinal fibres, resisting that of the circular fibres, gives the orifice an oval form. This eversion and contraction are produced by that series of motions which constitutes the peristaltic action of the intestines."—(*Travers on Injuries of the Intestines, p.* 85.)

According to this gentleman, some of these appearances were described by Haller, in *Element. Physiol. lib.* 24, *sect.* 2; and *Opera Minora, t.* 1, *sect.* 15.

Having witnessed the facility with which considerable injuries of the intestinal tube were repaired, Mr. Travers was desirous of ascertaining more fully the powers of nature in the process of spontaneous reparation, and of determining under how great a degree of injury it would commence, as well as the mode of its accomplishment. For these purposes, he divided the small intestine of several dogs as far as the mesentery. All these animals died, in consequence of the intestinal matter being extravasated, if they had been iately fed, or if they had been fasting, in consequence of inflammation, attended with a separation of the ends of the divided bowel, eversion of the mucous coat, and obliteration of the cavity, partly by this eversion, and partly by a plug of coagulated chyle.

In one particular instance, in which Mr. Travers made a division of the bowel, half through its diameter, a sort of pouch was formed round the injured intestine. "A pouch, resembling somewhat the diverticulum in these animals, was formed opposite to the external wound on the side of the parietes, by the lining peritoneum, on the other side, by the mesentery of the injured intestine, that intestine itself, and an adjacent fold, which had contracted with it a close adhesion. The pouch thus formed and insulated included the opposed sections of the gut, and had received its contents, &c. The tube at the orifices was narrowed by the half eversion, but offered no impediment to the passage of fluids."—(*P.* 96.) Whether, under these circumstances, the functions of the alimentary canal could have been continued, Mr. Travers professes himself incapable of deciding. Among the inferences which this gentleman has drawn from the experiments detailed in his publication, the tendency of the two portions of a divided bowel to recede from each other, instead of coalescing to repair the injury, merits notice, inasmuch as it tends to show, that the only means of spontaneous reparation consist in the formation of an adventitious canal, by the encircling bowels and their appendages. The everted mucous coat, which is the part opposed to the surrounding peritoneum, is also indisposed to the adhesive inflammation.

When, however, the wound of the intestine is smaller, the obstacles to reparation are not absolutely insurmountable. Here retraction is prevented, and the processes of eversion and contraction modified by the limited extent of the injury. If, therefore, the adhesive inflammation unite the contiguous surfaces, effusion will be prevented, and the animal escape immediate destruction. But union can only take place through the medium of the surrounding parts.

According to Mr. Travers, it is the retraction immediately following the wound that is a chief obstacle to the reparation of the injury; for if the division be performed in such a way as to prevent retraction, the canal will be restored in so short a time as but slightly to interrupt the digestive function. In confirmation of this statement, a ligature was tightly applied round the duodenum of a dog, which became ill, but entirely recovered, and was killed. "A ligature, fastened around the intestine, divides the interior coats of the gut, in this effect resembling the operation of a ligature upon an artery. The peritoneal tunic alone maintains its integrity. The inflammation which the ligature induces on either side of it is terminated by the deposition of a coat of lymph, which is exterior to the ligature, and quickly becomes organized. When the ligature, thus enclosed, is liberated by the ulcerative process, it falls of necessity into the canal, and passes off with its contents."—(*P.* 103, 104.)

It appears also from Mr. Travers's experiments and observations, that longitudinal wounds of the bowels are more easily repaired than such as are transverse. In a dog, a longitudinal wound of the extent of an inch and a half was repaired by the adhesive inflammation. Here the process of eversion is very limited; the aperture bears a smaller proportion to the cylinder of the bowel; and the entire longitudinal fibres resist the action of the circular, which are divided, and can only slightly lessen the area of the canal.—(*P.* 108.)

We come now to the consideration of the treatment of wounds of the intestines; a subject in which much difference of opinion has prevailed; principally, however, concerning the circumstances in which sutures are necessary, and the most advantageous way of applying them.

When the wounded bowel lies within the cavity of the abdomen, no surgeon of the present day would have the rashness to think of attempting to expose the injured intestine, for the purpose of sewing up the breach of continuity in it. In fact, the surgeon seldom knows at first what has happened; and when the nature of the case is afterward manifested, by the discharge of blood per anum, an extravasation of intestinal matter, &c., it would be impossible to get at the injured part of the bowel, not only because its exact situation is unknown, but more particularly on account of the adhesions, which are always formed with surprising rapidity. But even if the surgeon knew to a certainty, in the first instance, that one of the bowels was wounded, and the precise situation of the injury, no suture could be applied without considerably enlarging the external wound, drawing the wounded intestine out of the cavity of the abdomen, and handling and disturbing all the adjacent viscera. Nothing would be more likely than such proceedings to render the accident, which might originally be curable, unavoidably fatal. I entirely agree upon this point with Mr. John Bell, who says, "When there is a wounded intestine, which we are warned of only by the passing out of the feces, we must not pretend to search for it, nor put in our finger, nor expect to sew it to the wound; but we may trust that the universal pressure, which prevents great effusion of blood, and collects the blood into one place, that very pressure which always causes the wounded bowel and no other to protrude, will make the two wounds, the outward wound and the inward wound, of the intestine, oppose each other, point to point; and if all be kept there quiet, though but for one day, so lively is the tendency to inflame, that the adhesion will be begun which is to save the patient's life."—(*Discourses on Wounds, p.* 361, *edit.* 3.)

When the extravasation and other symptoms, a few days after the accident, show the nature of the case, a suture can be of no use whatever, as the adhesive inflammation has already fixed the part in its situation, and the space in which the extravasation lies is completely separated from the general cavity of the abdomen, by the surrounding adhesions.

When the bowel does not protrude, and the opening in it is situated closely behind the wound in the peritoneum, a suture is not requisite; for the contents of the gut, not passing onward, will be discharged from the outer wound, and not be diffused among the viscera, if care be taken to keep the external wound open. There is no danger of the wounded bowel changing its situation, and becoming distant from the wound in the peritoneum, for the situation which it now occupies is its natural one. Nothing but violent motion or exertions could cause so unfavourable an occurrence, and these should always be avoided. The adhesions which take place in the course of a day or two at length render it impossible for the bowel to shift its situation.

Things, however, are far different when the wounded part of the bowel happens to protrude. Here we have the authority of all writers in sanction of the employment of a suture. No enlargement of the outer wound is requisite to enable the practitioner to adopt such

practice; there is no disturbance of the adjacent parts; there is no doubt concerning the actual existence of the injury; no difficulty in immediately finding out its situation.

But though authors are so generally agreed about the propriety of using a suture in the case of a wounded and protruded bowel, they differ exceedingly, both as to the right object of the method, and the most advantageous mode of sewing the injured part of the intestine. Some have little apprehension of extravasation, advise only one stitch to be made, and use the ligature chiefly with the view of confining the injured bowel near the external wound, so that in the event of an extravasation, the effused matter may find its way outwards. Other writers wish to remove the possibility of extravasation, by applying numerous stitches, and attach little importance to the plan of using the ligature principally for the purpose of keeping the intestine near the superficial wound.

When the wound of a bowel is so small that it is closed by the protrusion of the villous coat, the application of a suture must evidently be altogether needless; and since the ligature would not fail to cause irritation, as an extraneous substance, the employment of it ought unquestionably to be dispensed with.

Supposing, however, the breach in the intestine to be small, yet sufficient to let the feces escape, what method ought to be adopted? The following practice seems rational. As Sir Astley Cooper was operating on a strangulated hernia, at Guy's Hospital, an aperture, giving issue to the intestinal contents, was discovered in a portion of the sound bowel, just when the part was about to be reduced. The operator, including the aperture in his forceps, caused a fine silk ligature to be carried beneath the point of the instrument, firmly tied upon the gut, and the ends cut off close to the intestine. The part was then replaced, and the patient did well. Mr. Travers, who has related this fact, approves of the plan of cutting away the extremities of the ligature, instead of leaving them hanging out of the external wound. It appears that when the first practice is followed, the remnant always makes its way into the intestine, and is discharged with the stools, without any inconvenience. But when the long ends are drawn through the outer wound, and left in it, they materially retard the process of healing.—(*On Injuries of the Intestines, &c. p.* 112, 113.)

Let us now inquire what ought to be the conduct of a surgeon, should he be called to a patient whose bowel is divided through its whole cylinder, and protruded out of the external wound.

Various have been the schemes and proposals for the treatment of this sort of accident; and since experience has furnished few practitioners with an opportunity of seeing such a case in the human subject, a variety of experiments have been made on animals, in order to determine what treatment would be the most successful. Ramdohr, indeed, is stated by Moebius to have had occasion to try on the human subject a plan, of which a vast deal has been said and written. He cut off a large part of a mortified intestine, and joined the two sound ends together by inserting the upper within the lower one, and fixing them in this position with a suture, the ligature being also employed to keep them at the same time near the external wound. The patient recovered, and the feces continued to pass entirely by the rectum in the natural way.—(See *Halleri Disput. Anat. vol.* 6, *Obs. Med. Miscellan.* 18.)

About a year after the operation the patient died, when the anatomical preparation of the parts was sent to Ramdohr by Heister. They were preserved in spirit of wine, and exhibited, according to the latter author, a union of the two ends of the bowel together, and *their consolidation with a part of the abdomen.* Now it has been questioned by a late writer, whether the union here spoken of ever really happened. When the upper end of the bowel is introduced into the lower, the external surface of the former is put in contact with the inner one of the latter; a serous membrane is placed in contact with a mucous one. These heterogenous structures, he alleges, are not disposed to unite. The mucous membrane, when inflamed, more readily secretes a kind of mucus, which would be an invincible obstacle to adhesion. He thinks it therefore more than probable, that, in the case related by Heister, the invagination was maintained by the union of the intestine with the corresponding part of the abdominal parietes. Several experiments on living animals have convinced him, that this happens, and that the mucous membrane will not unite with the external peritoneal coat. This impossibility of producing an immediate union between the mucous and serous membranes may of course be urged as an objection to Ramdohr's practice.—(*Richerand, Nosographie, Chir. t.* 3, *p.* 344, 345, *edit.* 4.) Another equally strong objection is, that the upper end of the bowel cannot be put into the lower one, unless it be separated from a part of the mesentery. Here the division of the mesenteric arteries may cause a dangerous bleeding. In vain did Boyer tie seven or eight of these vessels: his patient died with an extravasation in the abdomen.—(*Richerand, t.* 3, *p.* 343, *edit.* 4.)

Moebius attempted to repeat Ramdohr's operation upon a dog; but he could not succeed in insinuating the upper part of the divided bowel into the lower one, on account of the contraction of the two ends of the intestinal tube and the smallness of the canal. Moebius, therefore, was obliged to be content with merely bringing the ends of the bowel together with a suture: the animal soon afterward died of an extravasation of the feces.

Dr. Smith, of Philadelphia, also tried to repeat Ramdohr's method, but could not succeed. He divided the intestine of a dog transversely, and having inserted a piece of candle into that portion of the bowel which was supposed to be uppermost, he endeavoured to introduce the superior within the inferior; but the ends became so inverted that it was found utterly impossible to succeed. The scheme was therefore given up, and only one stitch made, the ligature being then attached to the external wound in the manner advised by Mr John Bell. The dog died, and on examination there was found a considerable quantity of feces and water in the abdominal cavity.

Two more trials were made of Mr. John Bell's plan by Dr. Smith, on the intestines of dogs: in both instances the animals died, the intestines being much inflamed, and feces effused in the abdomen.—(See *Dr. Smith's Thesis.*)

Mr. Travers likewise tried the same experiment. "I divided the small intestine of a dog which had been for some hours fasting, and carried a fine stitch through the everted edges at the point opposite to their connexion with the mesentery. The gut was then allowed to slip back and the wound was closed. The animal survived only a few hours.—*Examination.* The peritoneum appeared highly inflamed. Adhesions were formed among the neighbouring folds, and lymph was deposited in masses upon the sides of the wounded gut. This presented two large circular orifices. Among the viscera were found a quantity of bilious fluid and some extraneous substances, and a worm was depending from one of the apertures. By the artificial connexion of the edges in a single point of their circumference, and their natural connexion at the mesentery, they could recede only in the intervals, and here they had receded to the utmost." In another experiment, Mr. Travers increased the number of points of contact, by placing three single stitches upon a divided intestine, cutting away the threads and returning the gut. The animal died on the second day.—*Examination.* Similar marks of inflammation presented themselves The omentum was partially wrapped about the wound; but one of the spaces between the sutures was uncovered, and from this the intestinal fluids had escaped. On cautiously raising the adhering omentum, the remaining stitches came into view. Here again the retraction was considerable, and the intervening elliptical aperture proportionably large. On the side next to the peritoneum, however, the edges were in contact and adhered so as to unite the sections at an angle.

From such experiments, the conclusion drawn by Mr. Travers is, that apposition, at a point or points, is as respects effusion, more disadvantageous than no apposition at all; for it admits of retraction and prevents contraction, so that each stitch becomes the extremity of an aperture, the area of which is determined by the distance of the stitches.—(*P.* 116. 119.) This gentleman, therefore, maintains, *that the absolute contact of the everted surfaces of a divided intestine, in their entire circumference, is requisite to secure the animal from the danger of abdominal effusion.*—(*P.* 121.) The species of suture employed (says Mr. Travers) is of secondary importance, if it secures this contact.—

(*P.* 134.) And among other observations, I find "wounds amounting to a *direct* division of the canal are irreparable, and therefore invariably fatal."—(*P.* 133.)

These inferences do not appear to me satisfactorily established. We are told, that apposition at a point or points is, as respects effusion, more disadvantageous than no apposition at all, and that the absolute contact of the divided surfaces, in their entire circumference, is requisite to secure the animal from the danger of abdominal effusion. The foundation of these unqualified conclusions is five experiments made on dogs; in four of which experiments, the divided bowel was brought together with one stitch, on Mr. John Bell's plan, while, in another, three stitches were made; and yet, in all these instances, the animals died with the contents of the bowels effused. So far the inferences seem established. Unfortunately for their stability, however, Mr. Travers immediately afterward proceeds to relate other experiments, instituted by Sir Astley Cooper, Dr. Thomson, and Dr. Smith, which, though Mr. Travers seems unaware of the fact, tend most completely to overturn the conclusions which he had been previously making.

"Sir A. Cooper repeated the experiments of Duverger, who had succeeded in uniting by suture the divided intestine of a dog, including in it a portion of the trachea of a calf. In place of the uninterrupted suture, three distinct stitches were inserted. On the sixteenth day the animal was killed, and the union was complete."—(*P.* 123.)

Here are two facts, proving that a wounded intestine may be united, though the suture was not such as to maintain the divided surfaces in contact in the whole of their circumference.

Sir Astley Cooper then made the experiment, without including the foreign substance. The animal recovered, being a third fact tending to prove, that the absolute contact of every point of the ends of the divided bowel is not essential to the cure.—(See *A. Cooper on Inguinal and Congenital Hernia, chap.* 2.)

After dividing the small intestine of a dog, Dr. John Thomson, of Edinburgh, applied five interrupted stitches, at equal intervals, the ends of the ligatures were cut off, and the external wound was closed with a suture. This animal did not die of the operation, and when he was afterward killed, it appeared that the threads had made their way into the interior of the intestinal canal. Dr. Thomson repeated this experiment, and did not kill the animal till six weeks afterward, when the same tendency of ligatures to pass into the bowels and be thus discharged was exemplified.

These last two cases make five in proof that the absolute contact of every part of the ends of a divided bowel is not essential to prevent effusion, or the consequences of the wound from proving fatal; and several other experiments were made by Dr. Smith, of Philadelphia, who employed four stitches with similar success.

As far then as the majority of such facts ought to have weight, we are bound to receive the conclusions of Mr. Travers as incorrect and unestablished. I am only surprised that Mr. Travers himself, who has cited the particulars of all these last experiments, did not perceive that they struck directly at his own inferences. They are not only irresistible arguments against Mr. Travers's conclusion, that the union of a divided bowel requires the contact of the cut extremities in their entire circumference; but they are a plain denial of another position, advanced by this author, viz. that wounds amounting to a direct division of the canal are irreparable, and therefore invariably fatal.

With respect to the species of suture being of secondary importance, provided it secure the complete contact of every part of the everted ends of the divided bowel, I regret that Mr. Travers has omitted to institute experiments, in order to prove that any such suture can be practised, and if he has the ingenuity to apply it, whether the result would be for or against the conclusions which he has formed. The fact of the sutures always making their way into the cavity of the bowel, and being thus got rid of, appears to me highly interesting, since it shows the safety of cutting away the ends, instead of leaving them hanging out of the external wound, so as to create the usual irritation and inconveniences of extraneous substances. It seems that Mr. Benjamin Bell first recommended cutting the ends of the ligatures away, and reducing the bowel in this state into the abdomen, as he says, a considerable part of the remainder of the ligature will fall into the cavity of the gut.—(*System of Surgery, vol.* 2, *p.* 128, *ed.* 7.) We have seen that the experiments of Dr. Thomson confirm the observation, and those instituted by Mr. Travers tend to the same conclusion.

According to the latter writer, the following is the process by which a divided intestine is healed when sutures are employed. "It commences with the agglutination of the contiguous mucous surfaces, probably by the exudation of a fluid similar to that which glues together the sides of a recent flesh wound when supported in contact. The adhesive inflammation supervenes and binds down the everted edges of the peritoneal coat, from the whole circumference of which a layer of coagulable lymph is effused, so as to envelope the wounded bowel. The action of the longitudinal fibres, being opposed to the artificial connexion, the sections mutually recede, as the sutures loosen by the process of ulcerative absorption. During this time, the lymph deposited becomes organized, by which farther retraction is prevented, and the original cylinder, with the threads attached to it, is encompassed by the new tunic.

The gut ulcerates at the point of the ligatures, and these fall into its canal. The fissures left by the ligatures are gradually healed up; but the opposed villous surfaces, so far as my observation goes, neither adhere nor become consolidated by granulation, so that the interstice making the division internally, is probably never obliterated."—(*Travers on Injuries of the Intestines, &c. p.* 128.)

Notwithstanding I have carefully read all the arguments adduced by Mr. Travers in favour of stitching a divided bowel at as many points as possible, I still remain unconvinced of the advantage of such practice, for reasons already suggested. If a case were to present itself to me, in which a bowel, partly cut through, protruded, I should apply only a single suture, made with a small sewing-needle and a piece of fine silk. If the bowel were completely cut across, I should have no objection to attach its ends together by means of two or three stitches of the same kind. I coincide with Mr. Travers, respecting the advantage of cutting off the ends of the ligature instead of leaving them in the wound, as I believe he is right in regard to the little chance there is of the injured intestine receding far from the wound; and if the ends of the ligature are then of no use in keeping the bowel in this position, they must be objectionable as extraneous substances.

As confirming some of the foregoing observations, I would refer to the valuable writings of Scarpa and those of Dr. Hennen. The remarks of the former, to which I allude, being contained in the last edition of the *First Lines of Surgery*, need not be repeated. "The older practitioners (says Dr. Hennen) were very much averse from leaving any thing to nature in cases of abdominal injuries, although their universal employment of sutures ought to have convinced them how much she could bear with impunity; for there can be very little doubt that their uniform performance of the operation of gastroraphe was at least superfluous, if not positively hurtful. In the course of a very extensive practice, two cases only have come under my notice, where it was required to a wounded intestine, though frequently it may be needed for injuries to the parietes."—(*On Military Surgery, ed.* 2, *p.* 411.)

When the protruded intestine is mortified, which must be a very rare occurrence in cases of wounds, the treatment should be the same as that of a mortified enterocele.—(See *Hernia.*)

As Dr. Hennen observes, in the treatment of wounds of the abdomen, the violence of symptoms is to be combated more by general means than by any of the mechanical aids of surgery. The search for extraneous bodies, unless superficially situated, or they can be felt with a probe, is entirely out of the question. "Enlargement or contraction of the wound, as the case may require, for returning protruded intestine, securing the intestine itself, and promoting the adhesion of the parts, is all that the surgeon must do in the way of operation; and even in this the less he interferes the better."—(*On Military Surgery, ed.* 2, *p.* 401.)

The principal indication is to prevent a dangerous degree of inflammation. Hence bleeding and the antiphlogistic treatment are highly indispensable. Let not

the surgeon be deterred from such practice by the apparent debility of the patient, his small, concentrated pulse, and the coldness of his extremities; symptoms common in acute inflammation of the bowels, and, in fact, themselves indicating the propriety of repeated venesection. Wounds of the small intestines are attended with more dangerous symptoms than those of the large ones. All flatulent, stimulating, and solid food is to be prohibited. The bowels are to be daily emptied with clysters, by which means no matter will be suffered to accumulate in the intestinal canal, so as to create irritation and distention.

When excrementitious matter is discharged from the outer wound, it is highly necessary to clean and dress the part very frequently. Gentle pressure should also be made with the fingers, at the circumference of the wound, at each time of applying the dressings, for the purpose of promoting the escape of any extravasated matter. For the same reason the patient should always lie, if convenient, in a posture that will render the external opening depending.

After a day or two the surgeon need not be afraid of letting the outer wound heal up; for the adhesive inflammation all around the course of the wound will now prevent any extravasated matter from becoming diffused among the viscera. If the case should end well, the intestine generally undergoes a diminution in its diameter at the place where the wound was situated. When this contraction is considerable, the patient occasionally experiences colic pains at the part, especially after eating such food as tends to produce flatulence. As these pains usually go entirely off after a certain time, and no inconvenience whatsoever remains, the intestine may possibly regain its wonted capacity again. A more considerable constriction of the above sort has been known to occasion a fatal miserere. Even the intestine itself has been known to burst in this situation, after its contents had accumulated behind the contracted part. Patients, who have recovered from wounds in the intestines, should ever afterward be particularly careful not to swallow any hard substances, or indigestible flatulent food. On this subject the writings of Scarpa are particularly interesting.

In some instances intestinal matter continues to be discharged from the outer wound, either in part or entirely, so that either a fistula or an artificial anus is the consequence. A fistula is more apt to follow when an intestine has been injured by a ball, has been quite cut through, or has mortified. But numerous cases prove that this is not invariably the consequence, and that a perfect cure has frequently followed each of these occurrences.—(See *Anus, Artificial.*)

When an intestine is completely cut through, and the lower portion of the canal lies inaccessibly concealed in the abdomen, writers insist upon the necessity of promoting the formation of an artificial anus. In this particular case they recommend fixing the extremity of the intestine with a fine suture to the edges of the outer wound. In order to distinguish the upper end of the intestine from the lower, the proposal is sometimes made to give the patient a little milk, and to observe whether the fluid, after a time, issues from the mouth of the protruded gut. In the mean while fomentations are employed. If the upper end of the intestine be in the abdomen, these speculative authors even deem it justifiable, when the accident is quite recent, to dilate the outer wound, search for the hidden continuation of the bowel, and then sew the two ends together.

Practical surgeons, I believe, are right in attaching little value to such directions. "Indeed (says a modern writer), the surgical world have long since dismissed their fears about the intestine falling inwards, and about the difficulties of distinguishing between the right and the wrong end of it. The apprehensions of abdominal effusions are now all pretty well subdued. The occurrence is extremely rare, and when it does happen, we leave the poor wretch to die in peace, without searching after effused fluids, the nature of which cannot be known, or, if known, the information cannot, in the most remote degree, lead to recovery. I have never witnessed a case where any possible good effects could follow the paracentesis; for peritonitis, in its most exquisite form, has always preceded the symptoms, which would lead to the performance of that operation."—(*Hennen on Military Surgery, ed.* 2, *p.* 411.)

In some instances musket-balls pass into the abdomen, lodge there a considerable time, and are then voided through the intestinal canal; while in other examples they become encysted, and continue lodged the rest of the patient's life, without producing much, or indeed any inconvenience.

Contusions and other Injuries of the Abdomen.—A violent contusion of the abdomen may injure the contained viscera, without the occurrence of any external wound. It was in this way that the liver or gall bladder was ruptured in the boy mentioned by Mr. Fryer (*Med. Chir. Trans. vol.* 4); and that the vena cava was lacerated in the case which fell under the observation of Richerand, where a cart-wheel passed over a child's belly.—(*Nosographie Chir. t.* 3, *p.* 353.) In other instances the mischief is done to the intestines; and still more frequently the viscera, as well as the parietes of the abdomen, have only suffered a more or less forcible contusion. The effects of such violence are inflammation of the injured bowels, and their adhesion to the inside of the peritoneum. Thus, the stomach and intestines, the liver, and the gall-bladder, when inflamed from a blow upon the front of the belly, contract adhesions to the corresponding portion of the parietes, which has been also bruised, and is itself inflamed. When such inflammations suppurate (and, according to Richerand, it is their most usual course), on opening the abscess, the pus is found blended with the matter which the viscera contain or secrete. Thus the alimentary matter, and even intestinal worms, have been discharged with the pus on opening certain abscesses which communicated with the cavity of the stomach or bowels; and bile has been found blended with the matter of abscesses in the right hypochondrium.

When, in consequence of a blow upon the anterior part of the belly, the patient experiences in the situation of the injury a deeply-seated pain; when a tumour forms, and the symptoms indicate violence done to some of the adjacent viscera, the inflammation is to be opposed by every possible antiphlogistic means. But when, notwithstanding such treatment, the swelling increases and suppurates, the abscess is not to be opened until it is perfectly mature. The inflammatory symptoms, which precede its formation, indicate that there is an adhesion between the injured organ and the parietes of the abdomen. Without this adhesion, opening the abscess would be attended with more ris because the pus or other matter might become extravasated in the cavity of the peritoneum. For the same reason, in the examples of tumours caused by bile in the gall-bladder, J. L. Petit recommends deferring the operation of opening them, until the inflammatory symptoms evince that an adhesion has taken place between the fundus of the gall-bladder and the corresponding point of the parietes of the abdomen.

An adhesion of the abdominal viscera to the inner surface of the peritoneum may be induced by other causes besides the action of contusing bodies. A knife, a fork, a shoemaker's awl, a needle, and other extraneous substances incapable of passing throughout the alimentary canal, have been known to irritate the stomach or bowel, and to bring on adhesion of them to the parietes of the abdomen, where a tumour has formed, which, on being opened, has discharged the foreign body. The records of surgery abound in facts of this kind. A fistula succeeds the opening of the abscess, the alimentary matter escapes, and, if the aperture admit not of being healed by methodical compression, the intestinal canal between the fistula and the anus contracts; most of the contents of the bowels pass out at the preternatural opening, and the patient falls into a state of marasmus, the more quickly fatal, the nearer the injury of the intestinal canal is to the stomach.

A long-continued pressure on the epigastric region may cause an adhesion of the stomach to the peritoneum, and suppuration taking place at the part, a fistula, communicating with the cavity of that organ may be formed, and allow the victuals to escape externally.—(See *Richerand, Physiologie, t.* 1, *Chymification: Nosographie Chirurgie, t.* 3, *p.* 353—356, *edit.* 4.)

I shall conclude with repeating, that in the generality of injuries of the abdomen from external violence, whether wounds or contusions, the principal danger depends upon inflammation of the peritoneum. In the treatment, therefore the most necessary thing is to

prevent and oppose this perilous affection. Copious and repeated venesection, the application of leeches, mild aperient clysters, a low fluid diet, perfect rest, fomentations, and the warm bath are among the most effectual antiphlogistic remedies which, in such cases, are entitled to praise and confidence.

WRY-NECK. (*Caput Obstipum; Torticollis.*) An involuntary and fixed inclination of the head towards one of the shoulders; a disorder not spoken of by the ancients. It should not be confounded with a mere rheumatic tension and stiffness of the neck, nor with the faulty position of the head arising from deformity of the cervical vertebræ.

Tulpius, about the middle of the seventeenth century, recorded the cure of a boy twelve years old, who, from his earliest infancy, had had his head drawn down towards his left shoulder by a contraction of the scalenus muscle. Fomentations were applied in vain. The head could not be brought into the right posture, even with the aid of steel collars. A consultation was therefore held, in which it was decided to put the boy under the care of Minnius, a surgeon who had performed several operations with success in similar cases. A large eschar was first made with caustic; and the muscle which drew the head to one side was then divided with a knife. Tulpius, who has left a very confused account of the operation, observes, that it was performed with great slowness and circumspection, for fear of wounding the carotid artery and jugular vein. However, he offers one good piece of advice, which is, not to make any preliminary application of caustic, as it only causes useless pain, and cannot be of any service. He also recommends the operation not to be done little by little at repeated times; and says that the surgeon should make a complete division of the muscle at once, with the necessary degree of caution.

Job à Meeckren also treats of the operation for the cure of a wry-neck. He states that he had seen it performed on a boy fourteen years old. The tendon of the sterno-cleido-mastoideus muscle was skilfully divided with one stroke of a sharp pair of scissors, by a surgeon named Flurianus, and as soon as the incision had been made, the head resumed its right position.—(*Obs. Med. Chir. c.* 33.) Mr. S. Sharp believed that the wry-neck mostly arose from a contraction of the sterno-cleido-mastoideus muscle, which he proposed the division of, whenever the disorder seemed to proceed from this kind of cause. However, he made an exception of cases in which the disorder had existed a considerable time or from infancy. He remarks, that if the cervical vertebræ have grown in a distorted direction, the position of the head cannot be rectified. With these restrictions, the following is the operation which he recommends: a transverse incision is to be made through the skin and fat, of a size somewhat more extensive than the breadth of the muscle, and about one-third of its length from the clavicle. A probed razor is then to be passed underneath the muscle and to be drawn out, so as to make the requisite division of the part. After the incision has been made, Mr. Sharp recommends the wound to be filled with dry lint, and to be always dressed in a way best calculated to keep the extremities of the muscle from growing together again. For this purpose, he directs the cut ends to be separated from each other as much as possible, with the assistance of a bandage to support the head during the whole time of the cure, which he says will generally be about a month.—(*On the Operations of Surgery, chap.* 35.)

According to Mr. Sharp's account, this operation ought to be common. However, if attention be paid to the nature and causes of the disease, and to the differences resulting from whether the disorder be recent or of long standing; constant or periodical; idiopathic or sympathetic; dependent on spasm or merely on paralysis of the antagonist muscles; and, lastly, if it be recollected that the affection may be produced by other muscles besides the sterno-cleido-mastoideus; it will appear that cases in which the foregoing operation can be judiciously undertaken are not frequent.

With regard to the manner in which Mr. Sharp ope-

rated, Mr. B. Bell conceived that it was attended with hazard of wounding the large blood-vessels. But though it seems to me better to use a probe-pointed bistoury and a director than the kind of razor which Mr. Sharp employed, I do not coincide with Mr. B. Bell in thinking that the latter surgeon's plan was at all objectionable on the score of danger in respect to wounding the vessels. Some practitioners may even think Mr. B. Bell's method most likely to injure the large vessels; for he advises the operator to cut the muscle from without gradually inwards, as deeply as necessary.

Perhaps the most prudent method of operating, is to divide the clavicular portion of the contracted muscle near the clavicle, and even to cut out a sufficient piece to remove all chance of the two ends uniting again. This step would weaken the muscle considerably, and perhaps might answer every purpose. It might easily be accomplished by means of a director and curved bistoury, after making the requisite division of the skin with a common scalpel. Were this proceeding to produce only partial amendment, the sternal portion of the muscle might afterward be divided. A director should be passed under it, and the division made with a probe-pointed curved knife. In operating on a female patient, it might be advisable, with the view of avoiding a large scar, to make only a puncture, and pass the knife flatly against and close behind the sternal portion of the muscle, the posterior part of which could be divided by then turning the edge of the instrument forwards. In this manner, Dupuytren operated successfully in one instance.—(See *Quarterly Journ. of Foreign Med. No.* 20, *p.* 623.)

Any cause destroying the equilibrium between the sterno-cleido-mastoidei muscles, will produce a wry-neck. Thus, when one of them is affected with spasm, and acts more forcibly than the other, it draws the head towards the shoulder of its own side; but when one sterno-cleido-mastoideus is paralytic, while the other retains only its natural power, the balance of action is equally destroyed, and the sound muscle inclines the head towards the nearest shoulder. In paralytic cases, electricity (*Phil. Trans. vol.* 68, *p.* 97; *Gilby in London Med. Journ. vol.* 4, 1790), blisters, stimulating liniments, the shower-bath, sea-bathing, issues, setons, the application of moxa, and attention to the health in general, are the means affording the best chances of relief.

Although the wry-neck sometimes depends on the state of the sterno-cleido-mastoidei muscles, it is frequently owing to a shortening of the integuments. Louis often successfully divided contractions of the skin, which had kept the head drawn to one side for many years, and had been occasioned by burns. Some of these contractions, he says, might easily have been mistaken for a part of the sterno-cleido-mastoideus itself.

Mr. Gooch relates a case of wry-neck, which was caused by a contraction of the platysma myoides muscle. The patient was a young gentleman fourteen years of age, who had always enjoyed very good health in every other respect. For several months his head had been strongly drawn to one side by a constant contraction of the platisma myoides muscle, which was exceedingly rigid, especially about its insertion at the basis of the jaw; and from the angle of the os maxillare inferius to the chin, the skin presented an appearance like that of the cicatrix of a burn. The same side of the face, quite from the point of the chin, was much shrunk and distorted by the contraction of the muscle; and the corner of the mouth in particular was so drawn to one side and downwards when the patient turned his head, that a vast deal of deformity was the consequence. From the inferior part of the eyebrow, at the internal angle of the eye to near the top of the head, there was a kind of furrow upon the skin about half an inch broad, with a shining, polished appearance, like the cicatrix of a wound, and destitute of hair, which had fallen off. From the corner of the eye downwards, there was the same kind of appearance in a less degree. The patient was subjected to repeated attacks of spasms, which began at the insertion of the muscle, and terminated at the eye, attended with a great deal of pain. The ear, and also the temporal and frontal muscles, were sometimes affected in a similar manner. The parts in the course of the insertion of the muscle into the jaw-bone, were considerably thickened, without being in the least inflamed externally, and when touched, but not stretched, they were little painful. The subjacent muscles did not seem at all affected.

It appears from the account given by Mr. Gooch, that in the treatment of this affection, every known means had been tried, by the advice of the most eminent practitioners; but without effect. Mr. Gooch determined to try what benefit would be produced by the division of the muscle. He first divided the integuments a little below the jaw, and thus exposed the whole breadth of the platisma myoides muscle, the fibres of which seemed to be in a state of violent extension, especially when the patient's head was inclined towards the opposite side. Mr. Gooch then divided the muscle completely across, by a very careful dissection, until the fasciæ of the subjacent muscles were exposed. The patient was then directed to turn his head towards the opposite side, and Mr. Gooch had the satisfaction of observing, that the patient could perform this motion without the face and corner of the mouth being affected, as they used previously to be. The wound was treated in the ordinary way, and no particular symptoms arose. As soon as the inflammation had subsided, the patient was directed frequently to move his head about, in order to prevent any kind of stiffness which might ensue from the contraction of the muscular fibres, and the inelasticity of the cicatrix.

The patient was perfectly relieved by the foregoing operation, and had no return of the painful spasms, to which he had been previously subject. The side of his face, however, never recovered its proper degree of plumpness.—(*Chir. Works of B. Gooch, vol.* 2, *p.* 1.)

I have lately seen an elderly gentleman, who is afflicted with a wry-neck, for which several of the most eminent surgeons have been consulted; but they have not advised an operation, nor have any of their prescriptions been of service. The case is complicated with a constant tremulous motion of the head, and great weakness and unsteadiness of the upper extremities, so that the patient cannot put a glass or cup to his mouth, without using both hands for the purpose.

Whenever an attempt is made to cure a wry-neck, by dividing any of the muscles, or merely the integuments, it becomes necessary to take some measures for keeping the head in a proper position, during the treatment of the wound; lest, in consequence of the head inclining in the direction in which it was before the operation, the divided parts should grow together again, and bring the patient into the same condition in which he was before any thing had been done. With a view of preventing this unpleasant circumstance, Mr. Sharp recommends filling the wound with lint, and making it suppurate. Mr. B. Bell, on the other hand, advises the employment of a proper machine for keeping the head in a due position. Some writers think the use of a bandage sufficient for the purpose. In Dupuytren's case, the cut edges of the muscle were kept asunder by depressing the clavicle, and inclining the head to the opposite side. The first object was fulfilled by binding the hand on the same side as the operation firmly to the foot, the knee being bent; the last, by means of a roller applied round the head, and under the axilla of the opposite side.—(See *Quarterly Journ. of Foreign Med. No.* 20, *p.* 623.) Sometimes, the removal of a small portion of the affected muscle may be necessary in the operation.

Boyer met with a paralysis of the extensor muscles of the head, attended with a constant approximation of the skin to the sternum. The disease resisted every plan of treatment, and an apparatus for supporting the head was the only thing found of any use.—(See *Traité des Mal. Chir. t.* 7, *p.* 61, 8*vo. Paris*, 1821.) *Sharp's Treatise on the Operations of Surgery, chap* 35. *Blasius, Obs. Med. Rar. p.* 2, *No.* 1; *cure effected by operation. Z

ZINC. The preparations of this metal are of considerable use in surgery. With respect to the *sulphate of zinc*, it may be said to be generally the best emetic in cases where it is desirable to empty the stomach without the least delay, as in cases of poison; for which purpose, the common dose is ℈j. "As an external application, this salt dissolved in rose-water, in the proportion of gr. iss. to ℥j. of rose-water, forms an excellent collyrium in the latter stage of ophthalmia, after the inflammatory action has subsided; it is a good injection in a similar stage of gonorrhœa, and a lotion in some kinds of superficial inflammations. Of double strength, this solution is the best application that can be used in scrofulous tumours, after they have suppurated, and the abscess has been discharged." —(*A. T. Thomson, London Dispensatory, ed.* 2, *p.* 559.) A gargle of sulphate of zinc is often advisable for ulcerations of the mouth, tongue, or throat. ℞. Zinci sulphatis ℈j. Aq. rosæ ℥vij. Oxymellis ℥j. M. ft. gargarisma frequenter utendum. The *unguentum zinci*, composed of an ounce of the oxide of zinc, and six ounces of prepared lard, is a useful, astringent, mildly stimulant application; and is frequently employed in various cutaneous diseases, ringworm, sore nipples, and chronic inflammation of the conjunctiva of the eyelids.

SUPPLEMENTARY APPENDIX

TO THE

SURGICAL DICTIONARY

OF

SAMUEL COOPER,

EMBRACING ALL THE VALUABLE IMPROVEMENTS OF THE SEVENTH AND LATEST EDITION OF THE AUTHOR, PUBLISHED IN 1838,

TOGETHER WITH

ALL THE RECENT IMPROVEMENTS IN EUROPE SINCE THAT DATE, AND A RECORD OF THE MERITORIOUS OPERATIONS PERFORMED BY

AMERICAN SURGEONS

IN VARIOUS PARTS OF THE UNITED STATES; THUS BRINGING THE SCIENCE DOWN TO THE PRESENT TIME.

BY DAVID MEREDITH REESE, A.M., M.D.,

PROFESSOR OF THE THEORY AND PRACTICE OF PHYSIC, AND OF THE PRINCIPLES OF SURGERY IN CARLETON MEDICAL COLLEGE, VERMONT; AND PROFESSOR OF THE INSTITUTES OF MEDICINE AND MEDICAL JURISPRUDENCE IN THE WASHINGTON UNIVERSITY OF BALTIMORE; HONORARY MEMBER OF THE MEDICAL AND CHIRURGICAL FACULTY OF MARYLAND; MEMBER OF THE MEDICAL SOCIETIES OF MARYLAND AND NEW-YORK, &c., &c.

NEW YORK:

HARPER & BROTHERS, PUBLISHERS.

1854.

Entered, according to Act of Congress, in the Year one thousand eight hundred and forty-two, by
HARPER AND BROTHERS,
in the Office of the Clerk of the District Court of the Southern District of New York.

ALPHABETICAL LIST OF AMERICAN SURGEONS

WHOSE OPERATIONS OR CONTRIBUTIONS TO SURGERY ARE REFERRED TO EITHER IN THE NOTES, OR THE APPENDIX BY THE AMERICAN EDITOR.

PREFACE.

In the article "Surgery" in the former edition of this Dictionary, and which, from the necessity of the case, is still retained in the text, it will be seen that, actuated by a national feeling, which will be appreciated by every American, I complained of the omission of the just claims and sterling merits in this department to which the surgeons of the United States were entitled, and attempted, in my notes, to supply the author's lack of service. Mr. Cooper has responded in a manner so creditable to himself, and to the liberal profession of which he is a veteran, that in justice to him I here insert his response. In the preface to his last London edition, 1838, he says,

"In particular, it affords me peculiar gratification to have had an opportunity, in this seventh edition, of bringing under the notice of British surgeons the meritorious transactions of their brethren in the United States, where the same zeal for the advancement of Surgery, and the same just estimate of its value to society, are exemplified as in the mother-country. In Operative Surgery, the surgeons of no nation have exceeded them in decision, coolness, enterprise, and boldness; and however doubtful I may individually be respecting the real good likely, on the whole, to result to mankind from certain extraordinary achievements with the scalpel, which, as will be seen in the course of this work, have been performed in America, I give the surgeons of the United States, as I do to many surgeons in my own country, France, and Germany, who are smitten with the love of similar proceedings, the credit of being actuated by the zealous hope of being able, by such means, to extend the efficiency of Surgery to cases of the most desperate kind."

"This edition will not only be the means of diffusing the knowledge of what has been done in operative and other parts of Surgery by European and American surgeons, but it will prove that, however right Dr. Reese may have been in complaining of my not having formerly done full justice to the surgeons of the United States, it was not from any desire on my part to keep their transactions concealed, but simply from the fact that I did not then possess the information that has since reached me of their praiseworthy exertions."

Under the article "Jaw-bones, amputation of," he thus speaks:

"The operation of removing a considerable portion of the lower jaw-bone is stated by Dr. Reese to have been first performed by Dr. Valentine Mott. This claim I was not aware of at the time when the article *Bones, Excision of*, was delivered to the printer, nor have I, at the present moment, leisure to ascertain the point. 'Dr. Mott is not only the *first*,' says Dr. Reese, 'but the *only* surgeon who has amputated the bone successfully at the articulation, except (since) Dr. Cusack of Dublin.' (See *Amer. ed. of this Dict.*)"

"I am very glad to have had this opportunity of recording the claim of Dr. Valentine Mott to the merit of having first removed the lower jaw at the articulation. The achievements of this distinguished surgeon, to whom I had the gratification of being introduced when he lately visited University College Hospital, I shall always be as proud of noticing as if they were the performances of any British practitioner."

And appended to the article "Surgery" I find the following frank and manly paragraph:

"I regret that, in the last edition, due justice was not done to the meritorious surgeons of the United States of America. This happened, however, not from any want of desire on my part to pay the tribute of honour where it was deserved, but from my not being then in possession of the valuable information respecting the progress of Surgery in the United States, which I have since obtained from Dr. Reese's American edition of this Dictionary, and other sources. I most cordially join, then, in the observation that, in a history of this kind, mention ought to be made of 'the names of Drs. White, Dudley, Davidge, Dorsey, Shippen, Bard, Post, Mott, Gibson, Parrish, Barton, M'Clellan, Stevens, Warren, Smith, Jamieson, and a host of others, who have contributed by the pen and the knife to elevate this department of the profession: this will be admitted, unless the successful ligature of the subclavian, the common iliac, the internal iliac, and that of the innominata, the amputation of the hip-joint, and upper and lower jaw, the extirpation of the parotid gland, the exsection of the clavicle, and the cure of aneurism, by tying on the distal side of the tumour, be unworthy of record. Some of these operations,' continues Dr. Reese, 'had never been attempted in Europe till our surgeons had led the way; and by these, and other splendid achievements in Operative Surgery, had demonstrated their practicability and success.' In adverting to such merit in the surgeons of the United States, I feel all that heartfelt pleasure which arises from the remembrance of their close connexion with my native country by the ties of blood and language, and they may rest assured of my sincere esteem, and of my earnest wish to render full justice to them on every subject."

It is a source of gratification to me that my humble effort has been successful in acquainting our professional brethren in Europe with the real merits of my own countrymen, so many of whom have distinguished themselves by their exertions in behalf of science and humanity, and whose meritorious claims in surgery have never before been recognised or acknowledged. Mr. Cooper has, in this seventh edition of his work, incorporated all my numerous notes and additions on American Surgery, so that our national pretensions are now spread before the profession in Great Britain. A similar meed of justice has also been since awarded us in France; for in the second edition of Velpeau's "Nouveaux Elements de Medecin Operatoire," the author has manifested a commendable spirit of liberality and justice to American surgery which does him honour.

The following extract of a letter lately received from the venerable author of this Dictionary, addressed to the American editor of his work, will be gratifying to the profession, and its insertion here is due to Mr. Cooper.

"Woburn Place, Russell Square, London.

"I am glad to hear that you are about to undertake another American edition of the Dictionary of Practical Surgery, for you acquitted yourself so ably in the editorship of the former one, that not a doubt can be entertained about your very superior qualifications for the task. I know that numerous valuable observations and improvements in Surgery have been made in Europe and America subsequently to the publication of your first edition, and especially since the year 1830, when your notes were written. Perhaps in the last ten years, I may say with truth that Surgery has made greater progress than in any preceding space of time of the same length; hence there must be a necessity for much change in every general treatise on the subject, in order to

adapt it to the present state of the science, and to let it give a correct explanation of the theory and practice most approved of in those parts of the world where our noble profession is cultivated with the greatest degree of success. These remarks are especially applicable to the Dictionary of Surgery, which embraces the whole range of the subject, and, perhaps, has a more extensive circulation than any other book devoted to it. Into your new edition you will be able to bring not only all the new matter brought into my last edition, but other observations and improvements made by the talented surgeons of the United States, and either not known to me, or not within my reach at the period when I was writing. Whenever I arrive at a new edition again, your testimonials of the contributions of your distinguished countrymen will not be overlooked, and every endeavour will be made to do them justice. Believe me that I shall be most happy to shake hands with you in London, and that I am most faithfully yours,

SAMUEL COOPER.

"*Professor Reese, New-York.*"

In the present Appendix, which is all that I am enabled to add in issuing the new edition, my aim has been to avail myself of the new matter furnished by Mr. Cooper concerning transatlantic Surgery, and at the same time exhibit the improvements in Surgery which have been made in the Old and in the New World since his latest edition, which, it will be seen, are neither few nor inconsiderable. To name but a single example, the entire speciality of Orthopœdic Surgery has been added, this department having but dawned when that edition was issued. And, moreover, by attempting the record of the achievements of American surgeons, especially since my last edition in 1830, I have endeavoured to bring down the science of Surgery to the present date. My limited space has imposed the necessity of greater condensation than is consistent with good taste, and in some cases may have prevented me from doing full justice to the individuals concerned. Indeed, if I could have had greater space for amplification on some topics, the performance of my task would have been much more agreeable to my own inclinations. Under the circumstances, however, I have done what I could, and trust that the candour of my professional brethren will award me all that I claim, a disposition to do equal and exact justice to all, and to exhibit the individual claims of American surgeons with impartiality and truth.

THE AMERICAN EDITOR.

P.S. The most important improvements of Mr. Cooper's last edition, including new articles superadded and old ones rewritten, have been inserted entire in this Appendix, as well as a summary of everything which he has furnished either recent or valuable in transatlantic Surgery. All such improvements will be found designated by being *included in brackets*, with the *initial of the author* appended.

SUPPLEMENT.

[ABDOMEN. The BELLY. If the pelvis be reckoned as part of the abdomen, the latter may be said to extend from the diaphragm, which forms its upper boundary, down to the levatores ani, and from the transversales muscles in front, to the spine, quadrati lumborum, and iliaci behind. Thus comprehensively viewed, the abdomen appears to contain and protect all the organs of digestion situated below the œsophagus, together with the urinary and internal organs of generation.

The *epigastric region* contains the middle part and the pyloric extremity of the stomach, the left lobe of the liver, the hepatic vessels, the lobulus spigelii, the pancreas, the cœliac axis, the semilunar ganglia, the aorta, the vena cava, and the crura of the diaphragm. The *left hypochondrium* contains the large end of the stomach, the spleen and narrow extremity of the pancreas, part of the colon, the renal capsule, and the upper portion of the kidney. The *right hypochondrium* contains the right lobe of the liver, the gall-bladder, part of the duodenum, some of the ascending colon, the renal capsule, and upper portion of the kidney. The *right lumbar region* contains the ascending colon, the lower half of the kidney, and part of the jejunum. The *left* contains the descending colon, the lower half of the kidney, and part of the jejunum. In the *hypogastric region* are the convolutions of the ilium, the bladder in children, and in adults both the bladder and the uterus, if distended. The *right iliac fossa* contains the cœcum, the ureter, and spermatic vessels, and the *left iliac fossa* the sigmoid flexure of the colon, the ureter, and the spermatic vessels.

Although the upper boundaries of the abdomen are completely determined internally by the diaphragm, they remain quite undefined externally. The diaphragm being a movable partition between the chest and abdomen, alternately ascending and descending in respiration, must by such changes have the effect of occasioning a correspondent enlargement or diminution of one of these cavities at the expense of the other. Without attention to this fact, mistakes in diagnosis would be very frequent. A sword, entering at the same point and in the same direction, may penetrate the thorax, or the abdomen, or both cavities, according to the position of the diaphragm at the moment of the injury.

The functions of the abdomen essentially require that its capacity should be continually varying; and had its cavity been circumscribed by an osseous case, like that of the cranium, or by a construction like that of the parietes of the chest, such an arrangement would have been totally incompatible with the offices of the abdominal viscera. So convinced is Cruveilhier of the facility with which the abdomen accommodates itself to the varying quantity of its contents, that he regards the doctrine as perfectly erroneous which refers the irreducible state of some herniæ to insufficiency of space within the peritonæum. "What!" says he; "can we suppose a cavity in capable of receiving the bowels again, which will allow of eight or ten pounds of victuals and drink being suddenly introduced into it? and which, in tympanites, often becomes distended in a short time to twice or thrice its natural dimensions?" According to the judgment of this distinguished pathologist, the obstacle to reduction depends either upon adhesions, or a disproportion between the viscera and the passage through which they protrude, arising from hypertrophy of the omentum or mesentery, or the altered relations of the peritonæum, drawn down by the displaced intestines. But, though this explanation, so far as it goes, seems correct with reference to the causes of the impossibility of reduction, Cruveilhier's view should not lead us to forget that certain cases every now and then present themselves where the viscera admit of reduction; but their return into the abdomen is followed by so much pain and indisposition, that the plan of keeping them there is unavoidably renounced.

In the treatment of several diseases and injuries of the abdomen, the surgeon cannot proceed one step with safety to his patient without the light of anatomy. Hernia, wounds, paracentesis, abscesses, are all so many cases where a surgeon deficient in anatomical knowledge would be likely to adopt very inefficient measures, or commit the most fatal mistakes. A surgeon acquainted with the structure and extent of the sheath of the rectus would have no difficulty in selecting the most advantageous place for the puncture, when matter collects within that investment of the muscle; and the practitioner, aware of the exact course of the epigastric artery, would never run any risk of wounding it either in tapping a dropsical patient, attempting to take up the external iliac artery, or dividing the stricture in inguinal and crural herniæ.

On being first consulted, surgeons, as well as physicians, too often neglect to institute a careful examination of the external parts of the body. Thus, either from carelessness or mistaken delicacy, they deprive themselves of the most simple, ready, and sure means of recognising the nature of the patient's complaint. Some diseases of the chest and abdomen are strikingly expressed on the surface; either in a permanent change of configuration, or *in* a temporary alteration of the natural movements, or both. (*Forbes, in Cyclop. of Pract. Med.*, art. *Abdomen, Exploration of.*) When obstinate constipation, great pain, nausea, and vomiting occur, let the surgeon always be sure that these symptoms are not dependant upon hernia, the usual situations of which should be carefully explored. The methods of exploring the abdominal regions are three, viz., *inspection*, *manual examination*, or *palpitation*, as it is termed, and *percussion*. The assistance of the sight and touch alone is not what the practitioner should always be content with; for as there is more or

less gas within the alimentary canal, and considerable arterial trunks pervade the abdomen, the sense of hearing may be exerted with as much success in the investigation of diseases of this part of the body, as in that of diseases of the chest. The parietes of the abdomen being capable of relaxation, the viscera may be felt directly through them; and, as Cruveilhier justly remarks, this is the only visceral cavity admitting of such exploration. Frequently, by means of palpation, tender, enlarged, or indurated points may be detected. In the first instance, however, a careful inspection of the surface of the abdomen should always be made. The practitioner should consider whether it is more bulky or of less size than natural. Swelling and tension, combined with pain, and a small, frequent pulse, characterize acute peritonitis. In some cases, a circumscribed swelling points out the seat of the disease—the organ affected. How essential the knowledge of the various regions of the abdomen, and of the contents of each of them, will here be for the formation of a correct opinion, must be sufficiently manifest. In pregnancy, retention of urine, and encysted dropsy, the swelling has an oval or protuberant form; in ascites, a broader, more expanded shape. In lead colic, the parietes of the abdomen seem retracted, or drawn inward. When palpation is instituted, the abdominal muscles should be relaxed, and the patient's mind diverted from his case. The pressure should be made gently and gradually; for when it is too forcible and abrupt, the examiner's touch is confused, the patient is put to pain, and his muscles contract. According to Cruveilhier, it has even been known to occasion the death of children by lacerating the liver, or the spleen in a state of enlargement. In fact, this rude mode of palpation conveys to the surgeon no information which can be relied upon; for the uneasiness, or pain experienced, or the change of countenance, may be more owing to the roughness or force of the pressure, than to any disease in the region of the abdomen subjected to examination. In certain cases, like ascites, the exploration should be made, if possible, while the patient is standing up, because in this position the fluid gravitates, and renders the parietes of the abdomen tense, so that the fluid is more plainly distinguished.

The presence of gas or liquids may be detected by percussion; that of liquids, or any foreign body, being made manifest by the dull, dead sound, and the perception of fluctuation by the hand applied to the point opposite that which receives the percussion.

In diseases and injuries of the abdomen, the diagnosis is often attended with considerable obscurity. It might be supposed, that as the soft and yielding parietes of this cavity facilitate the manual examination of its viscera, the detection of any painful point about them, and the slightest change of their shape or volume, nothing would be more easy than to trace disease in this part of the body through its different stages with great precision. But, as Cruveilhier remarks, this is far from being the fact. The vast number of organs contained in the abdomen, their great movableness, the frequency of their displacement, the multitude of their diseases, the particular character of their vitality, which sometimes lets them attain a very serious state of disease, unattended by any urgent pain; and, lastly, the difference of thickness of the parietes of the abdomen in different individuals, are undoubtedly the circumstances accounting for the frequent difficulty in the diagnosis. In surgical as well as in medical cases, the same uncertainty is experienced. Thus punctured wounds of the abdomen are treated on general principles, because the practitioner seldom knows exactly what viscera are injured. The same observation is applicable to contusions of the abdomen. A man who had a hernia received the kick of a mule on the belly: severe colic and vomiting ensued; several surgeons believed that these symptoms arose from the hernia being strangulated, and recommended an operation. Cruveilhier objected to this proposal, which, however, was carried into execution: the patient died, and, on opening the body, the small intestine was found torn completely across. In the North London Hospital, a young man died this spring (1836) from the kick of a horse on the abdomen. During the four or five days which he lived after the accident, he frequently vomited, and the belly became considerably swollen. Effusion of blood or of the intestinal contents was foretold; but, until the *post mortem* examination took place, the exact nature of the injury remained doubtful. A laceration of the small intestines was then detected, attended with effusion of its contents. The man died of peritoneal inflammation.

Dr. Seymour, in his work on *Diseases of the Ovaries*, relates the case of a young woman, who, after suffering hectic fever, the cause of which was not apparent, suddenly complained of acute pain in the abdomen, and in a few hours expired. On opening the body, a large quantity of pus was found effused in the peritoneal cavity from an abscess of the right ovary. Dr. Tweedie met with an ovarial abscess of the size of an orange, where the prominent symptoms were incontrollable vomiting and sympathetic fever. (*Cyclop. of Pract. Med.*, art. *Abscess.*) I have seen several instances of ovarial cysts which had become inflamed after tapping, and secreted a puriform fluid. A woman had an ovarial tumour, supposed to be an ovarial dropsy. After death the cyst was found to contain twenty pints of well formed pus. (*North Amer. Med. Journ.*, 1826.)

In one case an abscess communicated with the cœcum, to which and the parietes of the abdomen the omentum had become firmly adherent. In this manner a circumscribed cavity was formed, containing ill-conditioned pus and three or four seeds of fruit, covered by earthy incrustations. (*Abercrombie on Dis. of the Stomach*, &c., p. 338.)

Abscesses of the liver are more common in hot than temperate climates. Frequently the liver becomes adherent to the neighbouring parts, and then the matter may be discharged through the parietes of the abdomen, or into the colon, stomach, duodenum, or gall-bladder; from which latter the pus may descend by the biliary duct into the bowels, and be discharged *per anum*, an instance of which is recorded by Malpighi. Abscesses of the liver have been known to make their way through the diaphragm into the pleura, or into the air-cells of the lungs, so that the pus was coughed up. Andral refers to one case, where an abscess of the liver communicated with the vena cava, and to another, where it burst into the pericardium. (*Anat. Pathol.*, t. ii., p. 601.) At the request of the late Dr. Pinckard, I examined the body of a woman, in whose liver there were nearly three pints of pus; the case was remarkable on account of the gall-bladder having been annihilated, with the exception of a

trivial portion of its fundus, which is now in my possession.

The kidney may be the seat of acute or chronic abscess. Sometimes the quantity of matter is small, and the texture of the organ but little changed. In other examples, the suppuration may be so copious that none of the original structure of the kidney is left, excepting its capsular investment, which is expanded into a cyst of considerable size, and filled with pus. I attended with Mr. Baker, of Staines, an old man, who had symptoms somewhat like those of stone, and one of whose kidneys was found, after death, converted into a cyst containing about a pint of purulent fluid. As Andral observes, renal abscesses are sometimes so large that they may be felt through the parietes of the abdomen. (*Anat. Pathol.*, t. ii., p. 633.)

Abscesses of the kidney may burst in the loins, or make their way into the peritoneum, the ureter, or the colon.

Mr. Loudon, of Leamington, sent me the particulars of a case where the pulsations of the aorta against a diseased liver, extending across the epigastrium, and occasioning a well-defined tumour at the pit of the stomach, had been mistaken for an aneurism of the aorta, which vessel was found perfectly sound after death.

I once visited with Mr. Miller, of Keppel-street, a thin old man for retention of urine, where the tumour, formed by distended bladder above the pubes, was attended with regular and strong pulsations, corresponding to those of the arteries.

I once attended with the late Mr. Ramsden a boy in Christ's Hospital, who had a considerable abscess in the lumbar region, attended with distinct and forcible pulsations, corresponding to those of the aorta.

Three or four years ago I was also consulted by Mr. Gilbertson, of Egham, in a case where an enormous abscess in the epigastric region was accompanied by pulsations as strong and synchronous with those of the heart as the throbbings of an aortic aneurism.—C.]

[ABSCESS (from the Latin *abscessus*). A collection of purulent fluid in the texture or substance of any part of the body capable of suppuration. If the pus is not within the tissue, but merely poured out into some regular and natural cavity of the body, where it forms an accumulation, the case is said to be one of *purulent effusion*, or of *suppuration* in the particular cavity affected, whether lined by a mucous, a synovial, or a serous membrane. When, however, the purulent matter is formed by a mucous membrane, where it invests any surface, passage, or duct, from which it is promptly voided externally, without producing any accumulation, the patient is said to have a purulent discharge. Familiar examples of this are seen in gonorrhœa and purulent ophthalmia.

When purulent matter is confined, and not infiltrated through the structure of an organ, it constitutes an *abscess*, the boundary of which is formed either by the tissue of the organ itself, or by what is termed an *accidental* tissue. In both cases, the formation of the boundary is accomplished by the effusion of coagulable lymph, which in the former produces the union and consolidation of the tissues of the organ in immediate contact with the pus, and thus prevents its diffusion; in the latter it forms a more or less perfect membrane over the whole of the surface from which the purulent secretion has taken place; and hence the pus being enclosed, as in a shut sac, the abscess is sometimes said to be *encysted*.

The cysts of abscesses have the power of absorption. In this manner, the occasional dispersion and subsidence of an abscess, without either bursting or being opened, is accounted for. The cysts must evidently be also secreting surfaces; for, after the pus has been discharged, the cavity is soon filled with purulent fluid again.

Abscesses cannot be produced in certain textures. Thus, they cannot take place in the dense structure of fibrous or cartilaginous tissue, nor in that of serous membranes. When pus is discharged from these tissues, it is effused either upon their surfaces, or into the cavities which they invest; but abscess never forms in their proper substance. It is the prevailing doctrine, that abscess can take place only in parts into which cellular tissue enters as one of their constituents; and that this tissue is more frequently the seat of abscess than any other. John Hunter explained that abscess is more common in superficial than deep-seated cellular tissue.

For an account of the tendency of abscesses to make their way to the surface of the body, or into a passage lined by mucous membrane; the theory of suppuration; qualities of pus; the general symptoms and treatment of abscesses; and other topics relating to this interesting subject, see SUPPURATION.

It is a contested point whether an abscess can ever take place unpreceded by inflammation. Although John Hunter has a section in his work on the blood, entitled "Collections of Matter without Inflammation," yet his doctrines are decidedly in favour of suppuration being an effect of inflammation. At the present day, I believe the best pathologists would mostly concur on this point with Hunter. Thus Dupuytren affirms that an abscess is never a primary disease, but invariably the effect or termination of a more or less intense and extensive inflammation of the living tissues. "Whenever," says he, "suppuration is observed in any part of our organization, whatever may be the qualities of the matter, we may be sure that some kind of irritation, acute or chronic, apparent or concealed, must have existed or must yet exist, either in the situation occupied by the purulent collection, or in some remote part which communicates with this point, and is the source from which the matter is derived." Dupuytren maintains that this proposition is founded on the most accurate pathological investigations, and admits of no exception, whatever may have been asserted respecting collections of pus, supposed to be the result of substances absorbed and circulated for a time in the vascular system. Whether abscesses form slowly or quickly; whether they attain a considerable size or remain within narrow limits; or whether they contain pus of one quality or another, inflammation of more or less intensity, according to circumstances, seems to Dupuytren, and, I may say, to the greatest number of modern pathologists, to be always being concerned in their production. To this subject, however, I shall return in considering particularly the process of *suppuration*, under which head the formation, symptoms, and treatment of abscesses generally will be described. (See also ANTRUM, ANUS, BUBO, EMPYEMA, HYPOPIUM, LUMBAR ABSCESS, MAMMARY ABSCESS, PHLEBITIS, SCROFULA, and WHITLOW.)—C.]

[ABSORPTION. The source of the lymph is

less certain than that of the chyle; for, even at the present day, M. Magendie, influenced by the possibility of injecting the lymphatics from the arteries, and by the uniform nature of the lymph, and its analogy to the blood, professes a belief, which was common many years ago, that it is not formed by the decomposition of the old particles of the body, nor by fluids absorbed from various surfaces, but that it is composed of the thinner parts of the blood, which, instead of returning by the veins to the heart, pass into the lymphatics, and are conveyed to that organ through the thoracic duct. The lacteals certainly have little disposition to take up anything but chyle; but, as Dr. Bostock has explained, "the lymphatics are capable of absorbing a great variety of substances, differing from each other most widely in their nature, so that it would almost appear as if, by a certain mode of application, any substance might be forced into them. Nor (says Dr. Bostock) is this conclusion affected by the hypothesis of M. Magendie; for, although we might agree with him in supposing that, in the ordinary operations of the system, the veins are the principal, or even the sole instruments in removing the materials of which the body is composed, yet we have unequivocal evidence that, when certain poisonous or medicinal agents are applied to their extremities, they may be received or forced into them, and conveyed into the circulation. The case of metallic or other medicinal substances that are taken up by the lymphatics, may appear to be less difficult to explain, because the absorption is generally produced by friction, or some mechanical process, which may be supposed to force the substance into the mouths of the vessels, or to produce an erosion of the epidermis, which may enable the substances to come into more immediate contact with the mouths of the vessels. We may also imagine that, when the component parts of the body are brought into close approximation with their capillary extremities, they are then taken up in the same way that the chyle is absorbed from the intestines." (*Elem. Syst. of Physiol.*, vol. ii., p. 583.) Many physiologists have little difficulty in conceiving how fluids can be taken up by the lymphatics, but rather stagger at the notion of this being also the case with the hardest solids. Others, however, accommodate their creed to both hypotheses, reconciling themselves to them by the argument that, if the minute capillary arteries can secrete this dense, hard matter, the small lymphatics can remove it. One example is not more difficult to comprehend than the other. Yet such reasoning throws little light on the questions, how are the solids prepared for absorption, and in what manner are they taken up? These, in fact, remain completely unanswered.

"What (inquires a judicious physiologist) are we to conceive of the intimate nature of this operation? If solution of the substance be necessary, we are at a loss to find a proper solvent; many of the substances are insoluble in water, or in the serous fluid which is found in the vessels; while, on the other hand, it is perhaps not easy to conceive how the substances can be absorbed without being previously dissolved, and still more so how the solids can have their texture broken down, and enter the vessels, particle by particle, as it were, and be suspended in the lymph in a state of extreme comminution?" These difficulties some physiologists, including Bichat, endeavour to diminish by arguing that the lymphatics must be supposed to act only upon the elements of every texture, and that, on this principle, the absorption of solids is as readily intelligible as that of fluids, the same elements frequently contributing to the composition of both.

While parts retain the vital principle, they resist the action of the absorbents. Dead matter is more easily acted upon by the absorbents than living; and, in fact, "no part can be absorbed until its texture is destroyed, and, consequently, until it is deprived of life. No substance can possibly enter the absorbents while it retains its aggregation, so that it necessarily follows that the preliminary step to the absorption of the body is its decomposition." (*Bostock, Elem. Syst. of Physiol.*, vol. ii., p. 585.) This able physiologist afterward explains, that by the death of a part, preceding its absorption, is here signified only "that it is no longer under the influence of arterial action. It therefore ceases to receive the supply of matter which is essential to the support of all living parts, and the process of decomposition necessarily commences." A better account of the subject appears to be that which, dismissing all metaphysical and chemical reflections upon the supposed death and decomposition of parts previously to their absorption, represents the absorbents as acting directly upon the individual atoms, particles, or elements of the various textures. We know nothing about the vitality of these atoms or elements in their separate capacity; supposing them to possess it, we know nothing of the moment when they part with it previously to their entrance into the absorbent system, just as we are completely ignorant both of the manner in which such elementary materials acquire the vital principle, and of the exact moment when they become thus endued.

It appears also, from various observations and experiments, that substances may enter directly into the bloodvessels, and thus get at once into the circulation, or else be conveyed from the surface on which they are placed, through it and the contiguous tissues, into the blood, by what M. Magendie terms *imbibition*. In both these modes, it is inferred that absorption does not necessarily require any action or assistance of the lymphatic vessels themselves, the commencement of which, upon every surface and in every texture, by innumerable orifices or mouths, is not regarded by some distinguished physiologists of the present day as a doctrine by any means well established. Of course, what Hunter would explain on this principle, they would refer to imbibition, in which the absorbed matter passes through the textures of parts into the circulation, or else gets more directly into the bloodvessels. —C.]

[AMAUROSIS. Here the endermic application of strychnia deserves to be remembered.

In the *amaurosis suddenly formed by exposure to vivid light or lightning*, we may clear out the alimentary canal with an active dose of calomel and jalap. Blisters may then be applied above the eyebrows; and if these fail, electricity, or the external use of strychnia, may be tried. (See *Middlemore on Dis. of the Eye*, vol. ii.) In such cases Magendie would probably rub an ammoniated ointment over the frontal nerve.

In *amaurosis from the gradual effect of any exposure of the eye to vivid light, or of hard study by light of lamps or candles*, the foregoing treatment would, I think, be less likely to answer. Here a slow inflammation of the retina has probably

been going on, followed by structural changes, the only chance of removing which must depend upon depletion, mercury, and perfect rest of the organ. (See *Mackenzie on Dis. of the Eye*, p. 928.)

In *periodical amaurosis*, attended with serious impairment or loss of vision, returning daily, weekly, or monthly, or at irregular intervals, the eye being little or not at all affected in the intermediate periods, the best means of cure are bleeding, purgatives, and counter irritation. This treatment is especially applicable to hemeralopia.

In *amaurosis excited by dentition*, the gums may be divided, mild laxatives and small doses of sirup of poppies given, and the child put into a warm bath. If amaurosis depend upon the irritation of a carious tooth, this should be extracted.

For *amaurosis from a partial wound or laceration of the supra-orbital nerve*, the best plan is to make a free division of it.

Of late, strychnia has been employed as a remedy for amaurosis. It seems to Mr. Middlemore that its use should be confined to cases in which the retina is in a state of atony from some cause acting *directly* upon its texture, or upon its texture through the medium of the general debility of the system. At all events, he is of opinion that it should not be resorted to when there is much vascular fulness either of the system or the retina, or a tendency to inflammation. Its effects are likewise to be most carefully watched. An atonic state of the retina, or of some part of the nervous apparatus of the eye, productive of amaurosis, when unconnected with a full plethoric habit of body, determination of blood to the head, or any tendency to apoplexy, or any structural change either in the retina or its immediate nervous relations, may be treated by means of strychnia, particularly if tonics and general stimulants have been already unsuccessfully tried. The bowels are to be first freely opened, and aperient medicine occasionally given during the use of strychnia. Mr. Middlemore puts a narrow blister above the eyebrow of the affected eye, or above each eyebrow, if both eyes are involved; and after the cuticle and serum have been removed, sprinkles a small quantity of strychnia upon the raw surface, commencing with the fourth of a grain upon each side. If vision be not improved, this quantity may be gradually increased to two grains; the part is also dressed with savine cerate. The strychnia is applied only once in twenty-four hours, and the eyebrow is preferred as the place for its action, on account of the probable special effect of the strychnia upon the supra-orbitary nerve, in addition to its other more general influence. If strychnia excite great local uneasiness, it may be blended with a little flour or powdered opium. Mr. Middlemore observes, that, if the patient should become sensible of occasional flashes of light before the eye soon after the commencement of this treatment, there would be great encouragement to persevere; but that, if vision should be not at all influenced or improved after the strychnia had been tried a fortnight in sufficiently powerful but not imprudent quantities, it ought to be discontinued. Strychnia appears to him to be well adapted to the case of miners, whose eyes are affected with incomplete amaurosis, and who have been accustomed to follow their employment by means of a very feeble light, and also to cases of impaired sensibility of the retina, occasioned by too great a delay in curing congenital cataract. (See *Middlemore on Dis. of the Eye*, vol. ii., p. 282.)

Strychnia has also been prescribed as an internal remedy for amaurosis.

The division into gouty and rheumatic amaurosis is more than doubtful.

"We can admit," says Mr. Lawrence, "that the nervous structure of the eye may be diseased in the rheumatic and gouty, as well as in other persons; but it will require clearer evidence than we possess at present to show that there are distinct gouty and rheumatic amauroses." (*Lawrence, Op.* cit., p. 491.)—C.]

[AMPUTATION. Mortification of a limb, after operation for aneurism, is another exception to the general rule of not amputating till the mortification has stopped. Where also gangrene arises from the obstruction of the circulation by an aneurism bursting, and its blood passing copiously into the cellular tissue of the limb, amputation should be performed without delay, though the mortification may not have stopped. An example of the success of this practice I have laid before the profession. (See *Med. Chir. Trans.*, vol. xvi.)

DISEASED JOINTS.

Excluding from present consideration the proposal to undertake the excision of some joints which are in particular states of injury or disease, I may observe that scrofulous joints, with diseased bones and distempered ligaments and cartilages, is another case in which amputation may become absolutely necessary. As Mr. Pott remarks, there is one circumstance attending this complaint often rendering it particularly unpleasant, which is, that the subjects are most frequently young children, so as to be incapable of determining for themselves, which inflicts a distressing task on their nearest relatives. All the efforts of physic and surgery often prove absolutely ineffectual, not only to cure, but even to retard the disease in question. Notwithstanding many cases admit of cure, numerous others do not. The disease often begins in the very inmost recesses of the cellular texture of the heads of the bones, forming the large articulations, such as the hip, knee, ankle, and elbow; the bones become diseased in a manner which will be explained in the article JOINTS, sometimes with great pain and symptomatic fever, sometimes with little of either, at least in the beginning. The cartilages covering the ends of these bones, and designed for the mobility of these joints, are totally destroyed; the epiphyses in young subjects are either partially or totally separated from the said bones; the ligaments of the joints are so thickened and spoiled by the distemper as to lose all natural appearance, and become quite unfit for all the purposes for which they were intended: the parts appointed for the secretion of the synovia become distempered in like manner. All these together furnish a large quantity of stinking sanious matter, which is discharged either through artificial openings made for the purpose, or through small ulcerated ones. These openings commonly lead to bones which are diseased through their whole texture. When the disease has got into this state, the constant pain, irritation, and discharge bring on hectic symptoms of the most destructive kind, such as total loss of appetite, rest, and strength, profuse night-sweats, and an profuse purgings, which foil all the efforts of medicine.

and bring the patient to the brink of destruction. (See *Pott on Amputation.*)

In these cases amputation is attended with more success when performed late than when undertaken at an early period, before the disease has made great advances. This is fortunate, as it affords time for a fair trial of such remedies as are best calculated to check the progress of the disorder. (See JOINTS.)

Whenever the disease of a joint is likely to terminate in anchylosis, amputation should not be resorted to, as a cure will be effected without it. (See ANCHYLOSIS.) In deciding to amputate or not, a great deal will depend upon the state of the patient's health and his kind of constitution, as well as upon the condition of the joint itself. Thus Depuytren relates the particulars of two cases of diseased elbow, with ulceration of the cartilages, abscesses, sinuses, &c. In one, where the constitution was decidedly scrofulous, the hectic disturbance severe, the emaciation great, and the strength rapidly declining, the patient, a child, could only be saved by amputation. In the other case, where the constitution was less deranged and the strength better maintained, Dupuytren brought the disease to a conclusion by anchylosis. (See *Dupuytren, Clin. Chir.*, t. iv., p. 250.)

Surgeons should generally refuse to amputate limbs merely affected with stiffness or deformity. Operations under such circumstances, termed by the French *opérations de complaisance*, are more frequently followed by fatal consequences than amputations in more urgent cases. (See *Depuytren, Clin. Chir.*, t. iv., p. 271.)

The ease with which the flow of blood through the largest arteries is commanded by manual pressure, is a fact attested by Dupuytren, who only employed the instrument which he terms the compressor in a few special cases. (See *Leçons Orales, &c.*, t. iv., p. 377; *Elements*, part iii., p. 361; and *Ed. Med. and Surg. Journ*, vol. xx., p. 44.) The following passage explains Mr. Liston's views of this subject: "In all cases, and in all situations and circumstances, hemorrhage can be restrained during the completion of the incisions, and during the employment of means to close the cut ends of the vessels, by means of very slight but exact pressure on the trunk of the principal vessel. (See also *Dupuytren, Leçons Orales de Clinique Chir.*, t. iv., p. 382.) *The point at which this should be applied should be at as short a distance as possible above the place of the incision, and, at the same time, above the origin of any branches which must be cut.* Not the slightest pressure should be made until the instant when the incisions are about to be commenced, so that no venous congestion may take place in the limb. All the blood in the limb below the incisions must necessarily be lost. The veins are more easily compressed than the arteries; and pressure made a short time before the operation may arrest the return of blood, while it may not stop its influx. Thus, engorgement of the lower part of the limb is produced, and the quantity of blood that must be lost is increased. For a similar reason, pressure sufficiently firm to stop arterial hemorrhage is to be continued till the principal branches are tied, and then entirely removed, for the continuance of even slight pressure will increase the flow of blood from the surface of the stump—blood flowing in, and being arrested in its venous return, trickles out through the open ends of the vein. If a circular band be used for the compression, such as the screw-tourniquet, it should be put on quickly, screwed up at once, and then the incisions should not be delayed one instant." The doctrines and practice of Baron Dupuytren I will notice in the article HEMORRHAGE. Baron Dupuytren did not employ the common tourniquet, nor any kind of compress furnished with a handle (see *Leçons Orales Clinique Chir.*, t. iv., p. 298); he sometimes availed himself of an instrument which he termed a compressor, and which makes pressure only on two opposite points of the limb. (See *Leçons Orales, &c.*, t. iv., p. 386.)

VARIOUS BAD CONSEQUENCES MAY FOLLOW AMPUTATION;

As, for instance, spasms of the stump, tetanus, hemorrhage, severe inflammation of the stump, abscesses and extensive sinuses, inflammation of the medullary membrane, necrosis (see *B. Phillips*, in *Lond. Med. Gaz.* for 1833, 34, p. 189), protrusion of the bone, phlebitis, and suppuration in internal organs and in various other parts of the body, hospital gangrene, neuromata, &c. Of these several complications, which may either interrupt cicatrization, or subject the patient to great and protracted suffering, or even lead to a fatal termination, some are common to many operations, others restricted to that which is now under consideration; some arise from external causes, others from internal. (See *Dupuytren, Leçons Orales*, t. iv., p. 425.) It is only necessary to enter into a part of these topics in the present place, because the others more properly belong to the articles HOSPITAL GANGRENE, NECROSIS, PHLEBITIS, STUMPS, SUPPURATION, and TETANUS.

OF NEUROMATA AFTER AMPUTATION.

Sometimes amputation has been found necessary a second time, in consequence of a morbid protuberance of the nerves of the stump—a change noticed by Molinelli, Morgagni, Lower, Arnemann, and Prochaska, and always attended with excruciating pain and great irritability of the part, and sometimes with retraction of the skin and protrusion of the bone. According to Mr. Liston, neuromata are more frequent after amputation of the arm and forearm than other amputations. The disease seems to him, however, to be less common than formerly, which he refers partly to flap-amputations having been more extensively adopted, and partly to the method of tying arteries, so as to include nothing else in the ligature. In the forearm I have never seen a neuroma follow amputation, and yet almost all the operations were circular. Sir Astley Cooper, in his Lectures, relates one instance of such a stump high up the arm, where, upon examination of the part near the axilla, a tumour was felt, which, when touched, made the patient jump as if he had been electrified. In this case, as the bone protruded, amputation at the shoulder was performed. In another example, where a leg-stump was in a painful, irritable state from a similar cause, Sir Astley Cooper effectually relieved the patient by removing the diseased end of the posterior tibial nerve. This plan should always be preferred to amputation, when it presents any chance of being efficient. In a third instance, amputation was repeated at the patient's desire, and the nerves were found enlarged, forming a ganglion which partly rested upon the extremity of the bone. Such a degree of irritation had been produced by it, that no part of the stump could be touched without exciting a kind of eleu

tric shock. In a case that occurred in the Middlesex Hospital, amputation of the thigh was performed a second time, in consequence of the first stump being thus diseased. A complete ganglion, or plexus of nerves, was found closely adhering to the removed portion of bone, having almost the appearance of cartilage. The os femoris was of an unusually small size, but the linea aspera larger than natural. (See *Lancet*, vol. i., p. 115; vol. iii., p. 192.) In the same hospital, Mr. Mayo also amputated at the hip, on account of the extreme sufferings caused by a diseased state of the nerves of a thigh stump. (See NEUROMA.) For some observations on the changes which occur in stumps after cicatrization, see STUMPS.

OF THE OBLIQUE OR OVAL AMPUTATION OF THE LEG.

The method adopted by M. Sedillot consists in dividing the integuments on the outer side of the leg obliquely, from before backward, and from below upward. The knife is then carried round the posterior part of the limb to its inner side from behind forward, and from above downward. The division of the integuments is next completed in front by a transverse incision, leaving an oval wound, with its anterior angle truncated.

The only difference in the process of M. Baudens from that of M. Sedillot consists in making the incision through the skin entirely oval, and letting the knife descend about an inch lower down in front than behind.

"One reason," says M. Malgaigne, "not mentioned by any writer, makes me prefer the oval even to the circular method. In the latter, the principle is to leave the integuments sufficiently long on every side to cover one half of the stump. Now the posterior integuments, on the retraction of the muscles, reach the centre of the wound more readily than the integuments in front, which have to pass and bend over the end of the tibia. The object then can only be fulfilled by allowing a greater length to the skin in front."—(*Manuel de Méd. Opér.*, p. 293.)

Oval amputation of the leg seems to me the most tedious and painful of all the modes hitherto proposed of removing this part of the limb. Nor can it be necessary, if care be taken in the other methods to save a sufficiency of the integuments in front of the limb, as advised in the descriptions already given of those operations.

AMPUTATION AT THE ELBOW-JOINT.

Dupuytren, convinced of the correctness of the principle that as much as possible of the upper extremity should always be saved, revived the practice of amputating at the elbow whenever the state of this joint and of the soft parts admitted of such operation. The forearm being slightly bent, a double-edged knife is introduced transversely in front of the joint from one condyle to the other, and a flap made of the soft parts of the upper and anterior part of the forearm. The flap is now reflected, the capsular and lateral ligaments cut, and the operation finished by the surgeon sawing through the olecranon from before backward. The brachial artery is not divided, but the radial and ulnar. The bleeding vessels having been secured, the flap is brought over the end of the humerus, and secured in this position with long straps of adhesive plaster.

When there is not a sufficiency of soft parts left for an interior flap, Dupuytren used to amputate at the elbow with the circular method, the first incision through the skin and fascia being begun three finger-breadths below the condyles. The integuments and fascia were then drawn upward, the knife applied just below the edge, and the muscles divided down to the bone. By next carrying the knife a little upward, and separating the soft parts from the bones, the joint was reached, and opened by cutting the lateral ligaments and forepart of the capsule. The operation was completed by dividing the olecranon with the saw. (See *Dupuytren, Leçons Orales de Clinique Chir.*, t. iv., p. 316.) Amputation at the elbow was practised by Dupuytren in ten or twelve examples with great success, and the method is highly commended by Mr. Liston. (See *Elem. of Surgery*, part iii., p. 381.)

[Dr. John Kearney Rodgers, of New-York, has twice amputated at the elbow, once after the method of Dupuytren, and once removing the olecranon during the operation.—REESE.]

AMPUTATION AT THE WRIST, OR RADIO-CARPAL ARTICULATION.

The hand may be amputated at the joint of the wrist whenever the disease does not extend too high, and a flap can be made either from the integuments of the back of the hand or from those of the palm. Lisfranc makes both an anterior and a posterior flap. The circumstances of the case should determine the choice. Here amputation may also be done by the circular incision. The scaphoid, semilunar, and cuneiform bones form a convexity which is almost entirely received in the concavity of the radius, the ulna having no connexion with this joint except through the intervention of the triangular ligament, and to the extent of about four lines. The styloid processes of the radius and ulna can be readily felt, and below them the articulation commences; but, as Malgaigne observes, the direction of the joint is less easily determined; and if, while the hand is extended, the wrist itself be alternately bent and extended, these motions will take place in the medio-carpal articulation, into which the surgeon might erroneously carry the knife. The following are the instructions given by M. Malgaigne for the avoidance of this mistake:

1. If the hand be extended very much backward, the apex of the angle formed with the forearm will denote the radio-carpal articulation.

2. The transverse projection of the radius forward may also be felt, the joint being one line below it, and about five lines above the cutaneous wrinkle between the palm and the forearm.

3. The situations of the ends of the styloid processes being determined, and a line drawn across from one to the other, the middle of the joint will be two lines and a half above such transverse lines.

4. If only the styloid process of the radius is perceptible, that of the ulna is known not to descend so far as it by two lines; and the middle of the joint is three or four lines higher.—(*J. F. Malgaigne, Manuel de Méd. Opér.*, p. 324.)

The projection of the pisiform and cuneiform bones beyond the level of the palmar surfaces of the radius and ulna must be remembered in the operation.

Amputation by the circular method is performed as follows: An assistant draws up the integuments, and the surgeon makes an incision through them all round the wrist, about an inch below the styloid processes. The skin may now be easily retracted nearly as high as the joint; a second incision, made so as to leave the pisiform

and cuneiform bones just beyond it, divides all the tendons on a level with the retracted skin. The joint is then to be cut into on one side or the other, under the guidance of the corresponding styloid process, and the knife directed through the articulation in a line answering to the posterior convexity of the scaphoid, lunar, and cuneiform bones. The radial and ulnar arteries are now to be tied, but the interosseous here seldom requires a ligature. The wound is to be closed with the line of it in the transverse direction, and the stump placed in a depending position, so that, if suppuration take place in the tendinous hecæ or under the fascia, the matter may not pass far up the limb.

In the *double-flap-amputation*, as executed by Lisfranc, the hand and forearm are placed in the supine position, and supported by an assistant, who at the same time makes pressure on the radial and ulnar arteries. The surgeon, with a narrow knife, transfixes the soft parts on a level with the styloid processes, and from the radius towards the ulna, or from the ulna towards the radius, according as he is operating on the right or on the left limb. The knife is then carried along the anterior surface of the carpus, and its edge inclined forward so as to make a semilunar flap about two inches in length. This flap being held back, another very similar one is made on the back of the wrist; the extensor tendons are then to be cut through nearly on a level with the articulation, the joint opened just below one of the styloid processes, and the disarticulation finished as in the circular method.

When the soft parts are so diseased that two flaps cannot be saved, the operation may be done with a single one, which should then be made somewhat longer.

[In several cases of injury from the bursting of firearms, by reason of the laceration of integuments on the palmar surface of the wrist, it has been found impracticable to have but one flap, and that brought from the back of the wrist. In these cases of amputation at the joint, I have not met with any impediment in making a good stump. There can be little doubt that it is preferable in all cases to amputate at the wrist for injuries of the hand, instead of operating midway upon the forearm or above the wrist, as some surgeons have been in the habit of doing. Not only is there less trouble in healing the stump over the end of the radius than over the ends of two bones, but fewer ligatures are required, seldom more than two; and, what is still more important, the patient will find the stump more useful to him in after life.—REESE.]

AMPUTATION AT THE HIP-JOINT.

The propriety of the operation in desperate cases is now perfectly established.

Thus, as M. Velpeau observes, a comminuted fracture, an osteo-sarcoma, a spina-ventosa, any incurable disease of the femur extending above its shaft; gangrene; in short, any disease reaching to the vicinity of the hip, and so serious as to require the removal of the limb, are cases for amputation at this joint, provided the acetabulum and the bones of the pelvis be unaffected. It is indispensable for gunshot wounds of the upper third of the thigh, combined with fracture. (See *Nouv. Elém. de Méd. Opér.*, t. i., p. 516.) It was performed by Mr. Mayo for a neuralgic affection of a thigh stump.

AMPUTATION AT THE SHOULDER-JOINT.

The head of the humerus represents nearly the half of a sphere, scarcely one third of which is received by the glenoid cavity of the scapula, the rest being contained in the exceedingly loose capsule of this articulation. The articular surfaces are held together principally by the deltoid, supra-spinatus and infra-spinatus, teres minor, and sub-scapularis muscles. The joint is also very much strengthened by the tendon of the long head of the biceps, and by the accessory ligament extending from the acromion to the upper part of the humerus. Above the articulation is a kind of osseo-fibrous arch, formed by the acromion, the coracoid process, and the ligament stretched between them. This arch projects more than an inch in front of the glenoid cavity, and descends farther in the direction backward than in that forward. (See *J. F. Malgaigne, Manuel de Méd. Opér.*, p. 328.) If we examine the anatomy of the shoulder from above downward, we first meet with the deltoid muscle, covered by the integuments, some fibres of the platysma, and a very thin fascia. Then we come to a loose cellular tissue, the tendons of the supra-spinatus, infra-spinatus, subscapularis, and teres minor, the accessory ligament and fibrous capsule, and the tendon of the long head of the biceps. Lower down we arrive at the scapular portion of the triceps; and then the brachial plexus of nerves, the axillary vessels; and, under the skin, the pectoralis major, the latissimus dorsi, and the teres major. The apex of the acromion is very perceptible just above the cushion of the shoulder, as well as the coracoid process more towards the chest. Between these bony points is situated a triangular interval, useful to be recollected by the practical surgeon, bounded outward and downward by the head of the humerus; above by the clavicle and acromion, or, rather, by the coraco-acromial ligament; and inwardly by the coracoid process itself. This is the place where the joint may be at once cut into without any impediment from the bones; and it is on the knowledge of this fact that Lisfranc proposed one of his methods of amputating at the shoulder. When the posterior border of the axilla is reflected towards the scapula, as Velpeau observes, the knife may be made to pass below the acromion into the superior and external part of the joint. In some persons, the acromion is much more prominent than in others; and occasionally it is considerably depressed, so that its humeral aspect forms a deep concavity. In childhood it is cartilaginous; and Velpeau found it in two adult bodies separable by a very slight effort, as an epiphysis from the spine of the scapula. (*Velpeau, Nouv. Elém.*, t. i., p. 428.) The course of the circumflex arteries, that of the circumflex nerve; the situation of the accessory ligament extended from the acromion to the humerus; and, in particular, the origin and track of the tendon of the long head of the biceps, between the fibrous capsule and the synovial membrane into the bicipital groove of the humerus; the mode in which the capsule is attached to the humerus just below its anatomical neck; the very open angle formed by the junction of the head with the shaft of the bone; and the circular shape of its head, requiring an incision of corresponding figure for the prompt division of the fibrous capsule, are all interesting points of surgical anatomy, without a due knowledge of which a surgeon cannot amputate at the shoulder with skill and judgment.

The principal methods of amputating at the

AMPUTATION.

shoulder are comprised under four varieties: 1st, the operation with one flap; 2d, with two flaps; 3d, by the oval method (*Scoutteten*); 4th, by a circular incision (*Alanson, Sanson*, &c.). Here one fact merits particular attention, namely, that no mode of amputating at the shoulder can be exclusively employed in all the cases requiring the operation, because the soft parts around the joint are frequently destroyed, or very much injured to a greater or lesser extent, so that the surgeon is obliged to save skin and muscles wherever he can find them. On this point Dupuytren fully agrees with the surgeons of the British army.

AMPUTATION OF THE FINGERS AND OTHER PARTS OF THE HAND.

Amputation of the fingers, or parts of them, is performed with one or with two flaps, or with a circular or an oval incision, and frequently required, either primarily or secondarily, on account of various accidents and diseases, as comminuted fracture, onychia maligna, necrosis, &c. The best surgeons all agree with Mr. Sharp, that in general the operation is most conveniently performed in their articulations, though exceptions sometimes occur in which it may be done elsewhere, and the phalanx divided with the cutting-pliers. Thus it occasionally happens that either the distal or the middle phalanx is torn off, and the end of the proximate phalanx exposed: here, instead of removing the whole of the middle or of the proximate phalanx (as the case may be), it will often suffice to take away the denuded portion of it with the cutting-pliers, and save a proper flap for covering the end of the remaining part. As Mr. Liston has explained, it is sometimes desirable to save as much as possible of the proximal phalanx when amputation is rendered necessary by diseases of the middle articulation, or of the distal extremity of the bone. In such cases two semicircular flaps are made by cutting from without, either on the lateral, or on the palmar and dorsal aspects, and the bone is divided either with a small saw or the cutting-pliers. (*Elements, &c.*, part iii., p. 374.) When an injury just includes the joint and no more, Mr. Guthrie deems it better to saw through the bone than to operate at the next articulation. (*On Gunshot Wounds*, p. 384.

AMPUTATION OF THE DISTAL AND MIDDLE PHALANGES.

The distal bones are but loosely supported by the anterior ligament, and behind by the extensor tendon: at the sides, however, they are much more closely held together by the lateral ligaments. Consequently, it is these which must be divided in order to lay open the joint freely. The line of the articular interval is nearly transverse. Between the distal and middle phalanx it is on a level with the palmar cutaneous furrow; but in the articulation of the middle with the proximate phalanx, it is a line and a half below the palmar furrow. (See *J. F. Malgaigne, Manuel, &c.*, p. 305.) In either of these joints the operation is done in a very similar manner; either with a single flap, taken from the palmar surface of the finger, and long enough to cover the whole surface of the wound, or with two flaps, the longer one being formed on the palmar side, and the shorter one on the back of the finger. The surgeon, taking hold of the finger and placing it in the bent position, makes, with a narrow bistoury, an incision (I should say a semilunar one) across the prominence of the articulation, or, as Malgaigne directs, half a line below it. Thus the skin is divided, and the posterior part of the capsule generally opened with the same stroke. If it be not, the surgeon, without stopping to effect this, may proceed to cut the lateral ligaments one after the other; and the knife being next conveyed through the articulation, the operation is completed by the formation of the palmar flap, which is to be the larger of the two, and long enough to cover the greater part of the wound. (See *Dupuytren, Leçons Orales de Clinique Chir.*, t. iv., p. 305; *Malgaigne, Manuel, &c.*, p. 306.) When both phalanges are to be removed, the dorsal incision should end on each side precisely on a level with the terminations of the cutaneous palmar furrow.

Another method, ascribed to Lisfranc, consists in attacking the joint on its palmar side. All the fingers are bent except that which is about to be amputated. The point of a narrow straight bistoury, with the edge directed towards the extremity of the finger, is introduced half a line beyond the palmar cutaneous wrinkle if we are amputating the distal phalanx, and exactly at the base of this wrinkle if we are removing the middle phalanx. The knife is to pass through the finger from one side to the other, and close to the lateral and anterior surfaces of the bone, along which it should be carried to the extent of six lines, and then brought out so as to complete a semilunar flap. The knife is then carried again to the base of the flap, to divide the anterior ligament. In this operation the lateral ligaments scarcely require to be cut separately; for the same stroke of the knife by which the anterior ligament is cut usually cuts them also, and makes room for the knife to be conveyed through the articulation. Lastly, the textures on the dorsal aspect are divided, without any posterior flap being made. By this method a more regular and better-nourished flap is produced, and the operation is more sure of being effected with precision; but the extensor tendon is apt to remain too long, in which event its projecting end should be cut off with scissors.

The *circular method* of amputating a finger is the oldest. The finger is put in the extended posture; a circular incision is made three or four lines beyond the articular interspace, the situation of which is denoted by the position of the palmar cutaneous furrow. The skin is dissected up as far as necessary, and the joint opened either in front or behind, as in the flap-operation already described. Or, if the disease or injury will admit of it, the integuments may be drawn up before the circular cut is made, and thus little or no dissection of them from the subjacent parts will be necessary. In general, after amputation of the distal and middle phalanges, the bleeding ceases as soon as the wound is brought together with adhesive plaster, and no ligature is required.

AMPUTATION AT THE METACARPO-PHALANGIAN ARTICULATIONS.

Each of these joints is of the enarthrosis kind, and furnished only with loose ligaments. What is termed the knuckle, or the articular prominence, seen when the phalanx is bent, is formed by the head of the metacarpal bone. The joint is commonly about ten or twelve lines above the digital commissure.

1st Method.—The hand being placed in the prone position, and the other fingers held apart

from the one about to be removed, the phalanx is to be bent, as Lisfranc specifies, to an angle of 45°, and an incision begun over the head of the metacarpal bone, about three lines beyond the articulation, and extended obliquely down to the side of the finger, on a level with the distal commissure, care being taken to divide as completely as possible the extensor tendon. The incision is then carried to the palmar aspect of the joint, and the first flap completed, which is to be reflected. The knife is now pushed into the exposed side of the articulation, the ligaments cut, and the operation finished by the formation of the opposite flap, which ends, like the first, at the digital commissure.

The following is Mr. Liston's description of this method: The operator seats himself before the patient, grasps the finger so as to manage its movements with the left hand, and, holding the knife perpendicularly, with its point upward, lays it over the knuckle, and carries it obliquely upward, so as to open that side of the articulation. He then pushes the finger towards the opposite side, and with the point of the knife completes the loosening of the articulation, which should never be done with the blade, as it would cross-cut and mangle the skin. After the separation of the base of the phalanx with the point, the blade is passed behind; and, being carried downward and outward, it forms a flap similar to the first. They are retained in contact by bringing the neighbouring fingers towards one another. In general, this will also stop the bleeding, but sometimes one or both digital arteries will require ligature. (See *Liston's Elements*, part iii., p. 375.)

When this operation is done on the index finger, the outer flap should be the larger; when on the little finger, the inner flap should have the greater size. (See *J. F. Malgaigne, Manuel, &c.*, p. 310.) Dupuytren, instead of cutting the integuments obliquely, preferred dividing them perpendicularly, and making a semilunar incision, directed from the dorsal towards the palmar aspect of the finger. Another semilunar flap was next formed on the opposite side. As Dupuytren found that, when the ring or middle finger had been removed, without taking away the head of the corresponding metacarpal bone, the adjoining fingers remained widely separated at their base, but obliquely approximated to one another at their extremities, so as to produce a considerable deformity, and an imperfection in their functions, he used not to be content with amputating the phalanges, but made it a rule to apply a retractor, and saw off the head of the metacarpal bone. (See *Leçons Orales, &c.*, t. iv., p. 309.) I know that Sir Astley Cooper has long advocated the same practice, which is most readily accomplished with a pair of strong cutting-pliers. The extension of disease to one of the metacarpo-phalangian articulations may also be another reason for taking away more or less of the metacarpal bone along with the finger. If merely the distal end of the bone is affected, the foregoing plan of operation will suffice; but, as is remarked by Mr. Liston, if a considerable portion of the metacarpal bone is to be taken away, the palm should be left uninjured. "With this view, the knife is entered over the dorsal centre of the bone, above the diseased part, and carried straight downward till near the articulation, when it is made to diverge for the formation of lateral flaps. The integuments in the track of the wound are then dissected backward so as to expose the bone completely, and the bistoury is passed round it throughout its whole extent, the edge being kept close to it. Then the bone is clipped at the proper point by the cutting-pliers; or the section of the bone may be performed before the separation of the soft parts from its under surface, as by raising the cut end this part of the operation may be facilitated." (See *Liston's Elements*, part iii., p. 377.)

AMPUTATION OF THE THUMB.

If merely the anterior extremity of the metacarpal bone were diseased, the bone might be divided with the cutting pliers, so as to remove the part affected, amputation being done either with the circular incision or a flap. (See *Velpeau, Nouv. Elém. de Méd. Opér.*, t. i., p. 389.) An operation more frequently practised, however, is disarticulation at the joint, between the metacarpal bone of the thumb and the os trapezium. The metacarpal bone is almost subcutaneous at its posterior and external aspect, but covered by a thick mass of muscle on the side towards the palm. The direction of the articulation is oblique, corresponding to a line, which, if carried far enough, would cross the root of the little finger. It has a loose capsule, and may be opened with the greatest facility at its two posterior thirds. The tendons of the long abductor and short extensor lie over the superficial side of it. The radial artery runs over its ulnar side in its way to the palm, to form the deep palmar arch. The tendon of the long extensor lies behind, and that of the long flexor in front of it. The place of the joint is readily determined by passing the forefinger over the dorsal aspect, or the sides of it, from before backward, for it is situated immediately behind the first bony tubercle. (See *Velpeau, Op.* cit., p. 390.)

1st Method.—While the thumb is held in the position of abduction, the knife is applied to the middle of the commissure; an incision is made at once down to the carpus, the edge being carried close to the ulnar side of the metacarpal bone, which is about to be taken away; the joint is then opened by cutting outward, the fibrous textures divided rather with the point than the blade, so as not to cross-cut the skin; the thumb abducted and dislocated, and a flap formed from behind forward, by carrying the knife close to the outer side of the bone, and a few lines beyond the metacarpo-phalangian joint. If the radial artery itself has been wounded, it must have a ligature; but, in other cases, bringing the flap accurately over the wound will stop the bleeding. Besides applying adhesive plaster, the flap, and especially its base, should be supported with a compress and bandage.

2d Method.—An assistant takes hold of the thumb, while the surgeon takes as much of the soft parts as possible with the fingers of his left hand, and draws them outward. The latter then transfixes them with a straight narrow knife from behind forward or towards the palm, directing the blade close to the radial side of the articulation. A flap is then formed; and, while this is held up by the assistant, the surgeon takes hold of the thumb, cuts through the joint from without inward, luxates the bone, and with the knife cuts through the middle of the commissure. This method leads to the same result as the former, but, being more difficult, ought not to be preferred.

3d Method.—Velpeau has frequently amputated the thumb in the following manner: An incision

is made along the back of the thumb from the styloid process of the radius to the commissure of the thumb and forefinger. This divides the integuments, the tendon of the long extensor, and a portion of the first interosseous muscle, so as to expose the joint. While an assistant holds aside the edges of the wound, the surgeon opens the capsule and dislocates the bone, which is then removed, care being taken to preserve as much of the flesh on the palmar side as will be required to close the wound immediately. Thus the palm of the hand is not at all wounded.

4th, or Oval Method.—The operation is begun as in the foregoing plan. The knife is carried round the anterior aspect of the root of the thumb, and then over the dorsal one, this second cut joining the extremity of the first. The point of the knife is next introduced into the articulation, which is cut through from its dorsal towards its palmar boundary. All that now remains to be done is to detach the bone from any fibres which may yet adhere to it, by carrying the knife in front of it from behind forward. The wound, when brought together, represents a straight line. (See *Velpeau, Op.* cit., p. 392.) This method was described by Lassus, Beclard, &c.

In flap-amputations of the leg, it appears to me that the anterior flap of integuments should be made longer, and the posterior flap of the integuments and muscles of the calf about one third shorter than is generally done. By this means the front of the tibia will be better covered, and the frequency of exfoliation diminished, while there will also be the advantage of the surface of the wound being considerably lessened below, where matter is disposed to form and lodge.

In the United States, amputation or exsection of the clavicle was performed for the first time by Dr. Mott in 1829. In the twenty-first volume of the *Med. Chir. Trans.* are the particulars of a similar operation executed by Mr. Travers. Other cases I have noticed in the article BONES, EXCISION OF. In Mr. Travers's case, the operation was performed on account of a tumour of the clavicle. "A crucial incision was made through the integument and platysma myoides, one limb of which was nearly in the line of the clavicle, and the other at right angles, and the flaps and fascial coverings successively dissected down to the external basis of the tumour. The pectoralis and deltoid muscles were then carefully detached from their clavicular origin, avoiding the cephalic veins, and the fibres of the trapezius and cleido-mastoid muscles divided on a director. One considerable vessel, in the situation of the transversalis humeri, required a prompt ligature. The circumference of the tumour was now well defined, though it was found to be firmly imbedded, and adherent on its posterior aspect. Disarticulation of the scapular extremity of the bone was next effected without difficulty; and the mobility thus communicated to the mass facilitated the completion of the operation. A director was now worked beneath the bone, as near to the sternal articulation as was practicable, and with a pair of strong bone nippers this introduced, it was completely and clearly divided. The subclavius muscle and a part of the rhomboid ligament were now detached from the tumour, and the mass being well raised by an assistant, while the edges of the wound were kept wide apart by metallic retractors, the cervical prolongations of the tumour were separated from their remaining connexions by a few touches of the scalpel, without injury to the subclavian vessels." The loss of blood did not exceed twelve ounces. The case terminated so favourably that there was scarcely any falling forward of the shoulder, nor any restriction of the motions of the arm. The young gentleman elevates it perpendicularly over his head, extends it horizontally, carries and rotates it behind the trunk, and performs the same extent and variety of circumduction, and with equal promptitude and power, as the parallel movements of the opposite arm. The production of bone from the truncated sternal extremity of the clavicle extends at least two inches, and terminates beneath the centre of the cicatrix in a firm ligamentous band, adherent to the skin. (See *Med. Chir. Trans.*, vol. xxi., p. 135, &c.)—C.]

[In the Amer. Jour. of the Med. Sciences, vol. xxii. and xxiv., Nos. 44 and 51, p. 356 and 135, Dr. Geo. W. Norris, of Philadelphia, has published two papers, entitled "Statistics of Amputation," drawn from the records of the Pennsylvania Hospital. They have been prepared with great discrimination and skill, and in point of practical importance possess great merit, as exhibiting the results of this operation in the greatest variety of cases. They are highly creditable to their author for their originality, this being the first report of the kind ever published. That they are appreciated by the profession at home and abroad, is shown in the fact that, since their publication, similar reports have been published by the Massachusetts, Liverpool, and University College Hospitals, and also by the Edinburgh Infirmary. The greatest benefits must result from these statistical publications in this and other departments of the profession, furnishing as they do the precise kind of information surgeons know how to estimate. The advantages of the numerical method in the collation of medical facts are becoming more and more obvious in every department.

That about one fourth of the patients subjected to amputation fail to recover, is the point which the statistical tables both of Dr. Norris, and Dr. Hayward of Boston, seem to establish; and hence our success in amputation would seem no better than that of European surgeons. That this may be true of hospital practice is possibly the fact; but to affirm that a similar proportion of fatal cases occur after this operation in private practice, is to do wanton injustice to American surgery. Professor Paul F. Eve, of Georgia, has denied the correctness of the inference sought from the foregoing statistics, and has published an article on the subject in the Southern Medical and Surgical Journal, and another in the Philadelphia Medical Examiner; and he appeals to the experience of Professor Mott and Professor Gibson in proof that deaths after amputation in private practice are very rare. Dr. Eve has himself amputated thirty-four times without losing a single case, and hence it was natural for him to remonstrate against the representation that one fourth of the patients die after amputation.

The venerable Dr. John C. Warren, of Boston, informs me that he has performed eighteen amputations of limbs in private practice, of which seventeen were successful. But the same operation in hospital practice has been much less prosperous in his hands, for out of forty cases, ten died after amputation. I have no particulars

in relation to the nature of the sequela which were fatal, although there are reasons which render any surgical operation in hospitals less successful than in private practice. The depraved constitutions and intemperate habits of the great majority of hospital patients are, perhaps, among the most frequent causes of untoward results, as well as the late period of the diseases or injuries requiring amputation at which even such patients will consent to go to the hospital or submit to the knife.

In the late number of the Boston Medical and Surgical Journal, April 14th, 1841, an interesting case is reported, in which amputation was performed for a tubercular disease of the elbow-joint, which had resisted Lugol's iodine treatment and all other medication, in the Massachusetts General Hospital. The operation was performed by the elder Dr. Warren.

Dr. Alban Goldsmith has had extensive experience in amputation, and has never lost a patient when the operation has been performed for disease. Amputation after accidents, injuries, fractures, burns, and the like, have been in his hands most generally fatal, which he ascribes to the shock the system has suffered in such cases. He thinks his uniform success in amputating for the removal of disease is owing to his diligence in supporting the system by quinine, wine, brandy, and other cordials, instead of depleting and reducing the patient, as is often done.

Dr. Mott, of New-York, has amputated at the hip-joint and shoulder-joint successfully. In amputations of the thigh, he prefers, after much experience, to transfix the limb, and make the double flap above and below. He has found primary amputations decidedly less successful than secondary, and, with a view to the result, always prefers the latter. In the occurrence of traumatic mortification, he amputates before this process is stopped, if the state of the general system will at all admit of it. So, also, in the mortification consequent upon tying a large artery for aneurism in the extremities, he advises a similar course.

In spontaneous mortification, or gangrena senilis, Dr. Mott has amputated four times while the mortification was spreading, the earlier period having been lost; once on the thigh, and three times on the leg. The thigh case and one of the leg recovered.

Secondary hemorrhage after amputation he has generally arrested by lint and pressure, with lint upon the stump. In one case he found it necessary to tie the femoral artery in the middle of the stump, which arrested the hemorrhage, but it soon returned. He then tied the femoral just at the crural arch, above the profunda, which was successful, and the patient recovered.

In dressing a stump, Dr. Mott has tried the plan of three or four stitches, and the application of cloths with cold water for the first day or two; but he greatly prefers to wait half an hour after all the vessels seem to be secured, for the occurrence of reaction, and, if there then be no hemorrhage, he adopts the old plan by sutures, adhesive straps, lint, compress, and roller.

Professor N. R. Smith, of Baltimore, reports in the American Journal of 1838 a case of peculiar interest, in which amputation of the thigh was successfully performed during progressive gangrene, resulting from a fracture of the thigh, in which the displaced fragment of the femur made pressure on the great artery and vein.

Dr. Nathan Smith, of New-Haven, performed amputation at the knee-joint for the first time in America in 1824, and with complete success.

Dr. Pancoast, of Philadelphia, has recently amputated at the knee-joint for necrosis involving the head of the tibia; the integuments of the leg were so diseased as to leave no alternative but to remove the limb at the knee-joint, or amputate the thigh. He chose the former, and performed the operation for the third time in this country. The result has been most satisfactory. The patient bears her whole weight upon the condyles, a mere pad stuffed with hair covering her wooden leg, and the woman does the whole work of a maid-servant in a large boarding-house.

In amputations of the leg, Dr. Pancoast slopes the incision backward towards the popliteal region, about an inch higher than the incision on the tibia. He has less flabby skin, a neater junction, less suppuration, and makes a better stump.

In amputating a leg for dry gangrene of the foot extending above the ankle, he found no necessity for a single ligature, the arterial trunks being closed with coagula and lymph. The stump healed kindly, and the patient is well.

Dr. J. C. Cheeseman, of New York, has recently amputated twice at the shoulder-joint with success. This surgeon has also tied the external iliac artery for aneurism; twice removed the tibia for necrosis, and during the last three years has operated four times for strangulated hermia, performed twelve amputations of the thigh, eight of the leg, and three of the arm, in the New-York Hospital. The proportions of deaths after amputation have been, as in most of the other hospitals, about one fourth of the whole number. He has cured ununited fracture of the thigh of long standing by excision of the ends of the bones.

Dr. Horner, of Philadelphia, has published an interesting paper on the subject of amputation at the shoulder-joint, with a description of a new instrument for securing deeply-seated arteries. I regret that I can only make reference to the Amer. Jour. for 1841 for the important practical matter it contains.

Dr. J. Kearney Rodgers, of New York, amputated at the elbow-joint with complete success in 1825, and Dr. Wagner, of Charleston, S. C., amputated successfully at the hip-joint a few years since. Dr. Mussey, of Cincinnati, has twice successfully amputated at the shoulder-joint.

Dr. Amasa Trowbridge, professor in Willoughby University of Lake Erie, has three times successfully performed amputation at the shoulder-joint. He claims to have been the first surgeon in the State of New-York who performed this operation. In this, however, he is mistaken, for his earliest date is 1809, while Dr. Bayley, of New-York, amputated at the shoulder-joint with success in 1792, and to him belongs the honour of being the first surgeon in America who attempted it. Professor Davidge, of Baltimore, repeated it soon after with similar success. Dr. Gibson has also performed this operation, and Dr. M'Clellan has repeated it six times with success. The latter surgeon has performed amputation at the neck of the thigh-bone with success. Dr. J. Rhea Barton, of Philadelphia, has amputated at the shoulder-joint with success, as also Dr. Gibson, the latter as early as 1812.

Dr. N. R. Smith has performed amputation of the larger limbs more than fifty times, and has only lost five patients. Similar success has attended this operation in the hands of Drs. Mott,

Stevens, Barton, Gibson, Warren, and, indeed, all the leading surgeons of this country, many of them in extensive practice never having lost a single patient after amputation. If dissimilar results have been witnessed in hospitals, according to Dr. Norris and Dr. Hayward, may it not in part be ascribed to the hot haste in which amputations of limbs are too often performed in public practice, and often upon patients whose members would be preserved, or, at least, the attempt made to preserve them, if the cases occurred in private practice? That unnecessary amputations, or those of even doubtful expediency, are more likely to prove fatal than those which are imperatively demanded, does not admit of a doubt among practical men.—REESE.]

[ANAPLASTIC OPERATIONS. Anaplastic or autoplastic operation is the generic name which has been given to the restoration of lost parts, by the transplantation of cutaneous or integumental flaps from adjacent sound parts, and relying upon the adhesive inflammation for effecting union, a portion of the transplanted integument being allowed to remain, by which the circulation may be carried on.

Of these operations several varieties have been reported to me by American surgeons, and I have in several instances witnessed their success. Dr. John Mason Warren, of Boston, has distinguished himself in this department by the number and by the success of his cases, some of which are reported at length in various periodicals.

Under the head of Rhinoplastic, it will be seen that Dr. J. M. Warren has employed discrimination in the cases, at one time adopting the Indian method, by borrowing the flap from the forehead, and at another a modification of the Italian operation of Taliacotius, in which the skin is taken from the arm. His modification consisted in dissecting the flap from the *forearm* instead of taking it from near the insertion of the deltoid muscle; a course which has many advantages when the flap desired is not larger than can readily be obtained from this locality.

Dieffenbach, of Germany, has perhaps done more than any other operator to elevate autoplastic surgery, not only in his own country, but in France; for, on a late visit to that country, free access to the hospitals of Paris was afforded him, for practising the different species of operations for the restoration of lost parts. The brilliant success of Dieffenbach, Graffe, and Labat on the Continent, of Liston in Great Britain, and Warren in the United States, has astonished the surgical world by the extent to which the different modifications of autoplastic operations are adapted.

Among the most important of these may be named the restoration of the lower lip and eyelid, after the excision of cancerous tumours, frequently practised by Dieffenbach; the closure of fistulous openings of the larynx and trachea, the vagina and urethra, &c., &c. The autoplastic method most generally adopted as applicable to these cases is that in which the flap required is taken in the immediate neighbourhood of the part destroyed, then slid along, and confined in the desired situation by the twisted suture. This is what the French writers call "autoplastie par glissement du lambeau." Dr. Warren has repeatedly succeeded in this operation for the removal of frightful deformities, and for supplying lost parts.

Dr. Mott, of New-York, has performed successfully the rhinoplastic, genioplastic, blepharoplastic, and urethroplastic varieties, for supplying a loss of substance by the transplantation and adhesion of sound integument upon the nose, cheek, eyelid, and urethra, as the names given to the several operations will indicate.

Dr. March, of Albany, has had complete success by the Indian method in two cases of rhinoplasty, and several other American surgeons have claims in this department, particularly Dr. George M'Clellan and Dr. T. D. Mutter, of Philadelphia, the latter of whom has had extensive opportunities in autoplastic surgery.

Under the article Staphyloraphy, it will be seen that Dr. J. M. Warren has had extraordinary success by adapting this autoplastic method to the cure of congenital fissures of both the hard and soft palate. The soft palate having been prepared for staphyloraphy by the usual abrasion of its edges and the introduction of the necessary points of suture, the mucous membrane covering the roof of the mouth was carefully raised on each side of the fissure in the hard palate, and when thus detached, they were brought across the fissure, and united like the soft palate by the interrupted suture, the flaps formed by the mucous membrane of the mouth being continuous with the denuded edges of the soft palate. Thus, by a judicious union of staphyloraphy and the staphyloplastic method, these shocking deformities are brought within the reach of surgery, even when there is extensive separation of the bones. In this operation Dr. Warren has done honour to himself, and earned this laurel for American surgery.

For the successful application of this operation to the lower eyelid by Dr. Warren, of Boston, Dr. M'Clellan, of Philadelphia, and Dr. Post, of New-York, see article Blepharoplastic. Dr. M'Clellan has also performed urethroplasty, genioplasty, and otoplasty. In the latter case the external ear was buried in the adhesions of the cicatrix following a wound of the head, and the deformity was remedied by dissecting out the cartilage, and elevating it to its normal position by flaps taken from the adjacent integument.

Dr. Pancoast has thrice succeeded with rhinoplasty, and has applied the autoplastic method for restoring the upper and under lip, and for contractions of the mouth, and has repeated blepharoplasty, urethroplasty, and cheiloplasty several times with success.—REESE.]

[ANCHYLOSIS. The following article having been re-written by Mr. Cooper, is deemed worthy of insertion entire.

ANCHYLOSIS (from ἀγκύλος, crooked). *True* or *complete* anchylosis signifies the fixed and motionless state of a joint, resulting from the articular surfaces being consolidated together by osseous matter. *False* or *incomplete* anchylosis denotes the loss of motion, or very considerable rigidity in an orbicular or ginglimoid joint, occasioned by adhesions of one synovial surface to the other, or by a thickening of the soft parts on the outside of the joint. By Mr. Mayo, anchylosis is divided into *osseous*, *cartilaginous*, and *mixed*, according as the articular surfaces happen to be united through the medium of bone, of cartilage, or of both these substances together. (See *Outlines of Human Pathology*, p. 72.) Of course, this last classification is not intended to comprise some of the varieties of false anchylosis. True anchylosis, then, may be said to denote an intimate osseous consolidation, either of the kind of joint termed *diarthrosis*, where the

ends of the bones are tipped with cartilage, and furnished with a capsular ligament, or of the other less movable sort of joint, termed *synarthrosis*, where the bones are united by an intervening layer of fibro-cartilage, and the articulation is strengthened externally by ligamentous bands. The latter kind of joint can hardly be said to be susceptible of false anchylosis; for it naturally has only a very slight degree of motion, which requires a true anchylosis for its interruption.

Anchylosis is more common in the ginglimoid articulations than others, though sometimes met with in every description of joint. In general, only one joint is anchylosed in the same individual; but sometimes several articulations are the seat of anchylosis, and rare instances are recorded in which every joint in the body was in this state. Thus, Bernard Conner describes an example of a general anchylosis of all the bones of the human body (*De stupendo Ossium Coalitu*). The particulars of a child, twenty-three months old, afflicted with universal anchylosis, are given in *L'Hist. de l'Acad. des Sciences*, an. 1716. In old age, anchylosis in certain parts of the skeleton is a natural change; and in this period of life it is common to find the heads of the ribs anchylosed to the bodies of the vertebræ, or the tubercles to the transverse processes, the vertebræ to one another, the enciform cartilage to the sternum, &c.

Anchylosis, strictly speaking, is not a disease itself, but only an effect or consequence of other affections, and it may follow all those which destroy any one of the conditions, without which the motion of a joint is necessarily interrupted, either permanently or for a very considerable time. The author of the article *Anchylosis*, in the *Encyclopédie Méthodique*, refers to a preparation, in which the femur is so anchylosed with the tibia and patella, that both the compact and spongy substances of these bones appear to be common to all of them, without any line of separation being discernible between them. Eustachius, Columbo, and Cruveilhier, have each seen an anchylosis of the lower jaw. In the Museum of the London University is a specimen of anchylosis extending to eleven vertebræ. In the same collection are examples of anchylosis between the occipital bone and the atlas, between the atlas and the dentata, and between the three upper cervical vertebræ. There may also be seen perfect anchyloses of the three bones of the knee, those of the elbow and hip, of the metacarpal bones to one another, and of the sacrum to the ischium. Cruveilhier has given the particulars of an anchylosis of one of the articulations of the lower jaw in a very old woman. It commenced in her childhood, from a blow on the side of the face. From the engraving of the parts, it appears that the condyle and glenoid cavity were completely consolidated and united by osseous matter.

Referring to anchylosis in general, we may observe with M. Sanson, that its causes are numerous, inasmuch as every circumstance capable of impairing the articular surfaces, stopping the synovial secretion, lessening the suppleness of the ligaments, or of the soft parts around the joint, or of interfering with the action of the muscles or the play of the tendons, may hinder the articular surfaces, more or less, from moving upon one another. One thing, almost essential to the production of anchylosis, is the part being kept motionless; and, as M. Sanson well observes, this condition has such influence, that it will of itself bring on the changes which terminate in a joint becoming incapable of resuming its functions in consequence of true or false anchylosis. An illustration of this fact is afforded by what happens to the Indian fakirs, who, by way of religious penitence, sometimes condemn themselves to continue motionless in certain attitudes for several years, and whose limbs at the expiration of the term are anchylosed in the posture in which they happen to have been so long maintained. The same fact is exemplified in persons who have met with fractures of their limbs; for, in consequence of the motionless state in which the part is kept to promote union of the broken bones, the synovial secretion is diminished, and the fibrous capsules and ligaments of the joint all acquire a rigidity in which the surrounding cellular tissue participates. The sheaths of the tendons are also no longer duly lubricated. All these circumstances make opposition to the free action of the muscles, which, being themselves weakened by protracted inactivity, are incapable of overcoming the resistance to the motion of the joint. On the same principle of a long-continued motionless state of an articulation, anchylosis may be induced as a complication and sequel of the contracted state of some particular muscle, or of the growth of various tumours near the joint. The contraction of cicatrices after burns, or after a destruction of the soft parts by gangrene or ulceration; and an unyielding state of the cellular tissue, the effect of extensive and inveterate abscesses in it; certain exostoses, and especially inflammation of the synovial membrane, whether acute or chronic, idiopathic, scrofulous, or rheumatic, &c., or accidentally excited by mechanical injury of the joints, are all so many circumstances capable of leading to anchylosis. Particular fractures of the joints, or such as are situated near them, if not skilfully treated, are apt to be followed by inflammation of the synovial membrane, absorption of the cartilages, and complete anchylosis. No doubt, in some of these instances, the connexion amounts at first only to what authors understand by false anchylosis; but, in the course of time, this becomes converted into complete or true, characterized by osseous consolidation. On the whole, however, as M. Sanson has remarked, false anchylosis is far more common than the true form of it.

When a bone is fractured near a joint, and this is kept too long motionless, anchylosis is apt to follow. Here the risk is increased by the synovial membrane being likely to inflame; and, indeed, sometimes the accident brings on ulceration of the cartilages. In the North London Hospital, I lately saw a case where the olecranon had been broken across its base, and the detached piece had become completely consolidated to the humerus; yet the patient had considerable power of extending the forearm, probably through the medium of the long supinator and other muscles arising from the outer condyle. It is partly in consequence of the risk of inflammation of the synovial membrane and of anchylosis that fractures of or very near joints are more serious than others differently placed. Wounds and contusions of joints may bring on such changes as terminate in anchylosis. I have already mentioned that Cruveilhier has seen an instance of anchylosis of the right articulation of the lower jaw. This was brought on by a blow received on the part when the patient (a female

was a child. She lived to a very advanced age, and, notwithstanding the anchylosis, was able to speak very well, and to masticate by pressing the food with her tongue against the hard substance covering the alveolary processes, where the teeth were deficient. (See *Cruveilhier, Anat. Pathologique*, livr. ix., pl. 5, figs. 1 and 2.)

With regard both to true and false anchylosis, the surgeon may generally render more efficient service in preventing, than in endeavouring to cure them. In wounds, contusions, and fractures of or near joints, the best means of prevention consist in the rigorous adoption of antiphlogistic treatment at first, and in a later stage in having timely recourse to passive motion of the joint; and then to combine with this plan friction with camphorated and other liniments, in order to promote the secretion of the synovia. When the bones are carious, as in scrofulous disease of the vertebræ, and in advanced stages of ulceration of the cartilages of the knee, elbow, wrist, &c., the surgeon, instead of endeavouring to prevent anchylosis, should promote its occurrence, as the most favourable result which the case now admits of. In fact, the completion of anchylosis will denote the termination of the disease. One important indication, however, under such circumstances, is to try to let the limb be anchylosed in the posture which will allow it to be of the greatest possible use. Thus, when the elbow is likely to be the seat of anchylosis, the forearm should be kept bent; but when the knee is concerned, the leg should be kept extended; and when the hip, the thigh should be maintained in a similar position. If anchylosis should have taken place to a certain extent, with the limb in a disadvantageous posture, this may often be still very much improved by the application of splints, and other mechanical contrivances. The action of any mechanical apparatus, however, must be at first moderate, though unremitting. Perseverance will here succeed, when violence would fail by bringing on excessive pain and a dangerous degree of inflammation. Indeed, where the attempts to remove a false anchylosis by gentle passive motion, embrocations, and the cautious use of mechanical means, fail, it is better not to employ violence, because such an anchylosis is preferable to inflammation, abscesses, and ulceration of the joint.

As for true anchylosis, where a complete osseous consolidation has taken place, it may be set down, not only as incurable, but as admitting of no improvement or alteration in the position of the limb, and, whatever that may be, the patient must be content with it. Hence, where there is risk of anchylosis, the great importance of placing the limb in good time in the position which will let it be of the greatest service to the patient.

Mr. Barton, one of the surgeons to the Pennsylvania Hospital at Philadelphia, made, a few years ago, the bold attempt to cure an anchylosis of the hip-joint by a surgical operation. (See *North American Med. and Surg. Journ.* for April, 1827.) The patient was a young sailor, who had fallen into the hold of a ship, injured the hip, and remained seven months without surgical assistance. He was now admitted into the above hospital, under Mr. Barton. The injured thigh, which was the right one, was in the bent position, with the knee drawn across the lower part of the left femur. The outer edge of the foot was placed forward, and the sole turned outward. A suspicion of dislocation was immediately entertained; but so great was the swelling, and so acute the pain in the hip, that Mr. Barton was deterred from making a manual examination to ascertain the fact. As soon as these symptoms had subsided, the limb was kept for several weeks extended in an apparatus, but without producing any elongation, or change in its position. Indeed, a complete anchylosis between the femur and os ilium had taken place. After a year's consideration, Mr. Barton, seeing that the case was beyond all common means of relief, determined to attempt to make an artificial joint. For this purpose he made in the upper part of the thigh an incision six or seven inches long, the middle part of which corresponded to the great trochanter. The centre of this first cut was crossed by another four or five inches in length, at a right angle. These incisions divided, in succession, the skin, the fascia lata, and muscles, so as to expose the anterior and posterior part of the femur, between the great and little trochanters. The femur was then sawn through between the great trochanter and the neck of the bone. The operation was completed in seven minutes; and, as soon as it had been done, the limb was easily brought into its proper position again, and found not to be more than about half an inch shorter than the other. The wound, which bled but little, was now closed, and the limb put up in a suitable apparatus, with one of Desault's splints. At first, the inflammation, swelling, and inflammatory fever were severe; but in nine days these symptoms abated, and the wound suppurated favourably. Suffice it to add, that the patient could move his thigh in all directions, and was able to get up; and in four months he was able to walk a considerable distance. He could by this time move the foot twenty-four inches forward, twenty-six backward, and twenty laterally, and rotate it six inches inward or outward. The limb was strong, and so trivially shortened, that the patient walked very perfectly. Behind the new joint was a deposite of bone, supporting the femur in this direction, and preventing its dislocation. Although the successful result of Mr. Barton's operation is what his boldness fully deserved, I agree with M. Sanson in thinking that doubts will be entertained by many judicious surgeons whether the proceeding, which actually put the patient's life in jeopardy, was really indicated.—C.]

[Notwithstanding the opinion expressed by Mr. Cooper and M. Sanson adverse to the surgical propriety of Dr. Barton's successful operation, while they commend its ingenuity, boldness, and success, this same gentleman has gained for himself and the profession new laurels by another and original operation for the removal of a shocking deformity of the knee-joint by anchylosis, the knee being bent at right angles with the thigh. A full report of the case may be found in the American Journal of Medical Sciences, and cannot fail to excite the admiration of the surgical world as a brilliant illustration of the triumphs of our art.

A free incision being made into the anterior and inferior portion of the thigh, exposing the femur a short distance above the knee, Dr. Barton proceeded with the saw to excise an angular portion of this bone, the apex of the triangle being near the posterior surface, carefully preserving the continuity of its shaft by leaving a thin ledge of the os femoris still untouched. The triangular portion being removed, two cut surfaces

of bone were left, with a vacuity increasing in width from the apex to the base of the triangle. These two surfaces were gradually approximated, aided by suitable manipulations, and as they approached each other, the leg was extended until, the union of the two bony surfaces being accomplished, the limb was brought down to a position occasioning very little deformity or inconvenience, and adapting it to all the purposes of locomotion. Complete success attended this new and original improvement in surgery.

Dr. J. Kearney Rodgers, of New-York, reports an operation for anchylosis of the hip-joint, suggested by the success of Dr. Barton. An incision was made down to the os femur, and this bone sawed through immediately above the trochanter minor. The limb, which had been greatly abducted, was now readily placed parallel with its fellow. But, as it was desirable to shorten the limb to conform to its fellow, which had been shortened by a fracture, another section was now made with the saw in the femur, and a wedge-shaped portion removed. The result of this operation was as gratifying to the patient as it was creditable to the surgeon who executed it. Two years afterward he paid a visit to Dr. Rodgers to express his gratitude for the restoration of his powers of locomotion.

Dr. Gibson, of Philadelphia, has lately performed a similar operation to the second case of Dr. Barton for angular anchylosis of the knee-joint. This case, which was completely successful, is reported at length in the American Journal for July, 1842.

FALSE ANCHYLOSIS OF THE KNEE-JOINT.

In the American Journal of the Medical Sciences for January, 1842, p. 101, Dr. Heber Chase has given the history of several cases of false anchylosis of the knee, cured by means of regular and gradual extension upon an apparatus with a screw and joint at the knee, similar to that recommended and employed by Mr. Liston of London, and Dr. Detmold of New-York. The results of Dr. Chase tend to show that in most cases false anchylosis of the knee, with appreciable motion of the joints, is readily curable in a reasonable time without the aid of tenotomy, and without material pain to the patient. The straightening of the limb has been effected in every instance, and the free use of the joint has been ultimately regained in the majority of cases. It is found *absolutely essential to success*, and the prevention of relapses, that the limb, when properly extended, should be retained in that attitude from one to two months before even commencing the passive or voluntary motions necessary to give free play to the articulation.—REESE.]

[ANEURISM. An aneurism may then be defined to be a tumour filled with blood, either in a fluid or solid state, usually attended with pulsation, and the sac of which has an opening in it, by which it communicates with the artery, from which the blood is transmitted into it. Lisfranc defines it "a tumour formed by arterial blood, and communicating with an artery," and divides all aneurisms into *traumatic* and *spontaneous*, according as they happen to be produced by a wound, or disease of the coats of the artery. (*De l'Oblitération des Artères dans les Aneurismes*, p. 6.)

Mr. Cooper has placed the following in his Addenda:

Since the article aneurism was printed, the arteria innominata has been tied by Mr. Lizars, but with the same unfortunate success as has followed all other examples of this operation. Under these circumstances, ought the practice to be continued? I think not, especially with the evidence in favour of tying the carotid.

Subsequently to the period when the article Aneurism was corrected, Mr. Liston, in a case of subclavian aneurism, situated very close to the outer edge of the right scalenus anticus, took up the right subclavian and right carotid at their origins, by which measure it was hoped that the innominata would become completely plugged up with coagulated blood, and the former vessels have a better chance of being permanently closed than if a ligature had been applied to the much larger vessel, the innominata itself. The suggestion was made by Mr. Quain. In fact, previously to the patient's death from hemorrhage, on the tenth day after the operation, the innominata became perfectly blocked up with solid blood; the ligature had come away from the carotid, and was found lying loose in the wound, with the two orifices of the artery above and below separated by an interval of more than an inch, and permanently closed. The ligature on the subclavian had not separated, but the root of that vessel, on the side towards the heart, was closed; and the hemorrhage had taken place from an ulcerated opening in the portion of the artery on the distal side of the ligature. My friends, Sir Astley Cooper, Mr. Vincent, and some other surgeons of great experience, have noticed that, when secondary hemorrhage occurs after operations for aneurism, it is most frequently produced by ulceration of the vessel on the distal side of the ligature.

When an aneurismal sac is formed upon a dilated artery, the walls of the vessel are sometimes thinner than usual; and some parts of them may become expanded into pouches, or even ingrafted upon the original swelling, the prominent points being always the thinnest. This kind of case is sometimes termed a *sacculated aneurism*, of which there is a good specimen in the Hunterian collection, remarkable also as exhibiting an aneurism opening by ulceration into the pulmonary artery. (See *Guthrie Dis. of Arteries*, p. 59.)

Aneurism by dilatation is distinguished by Breschet into four varieties, the names of which are determined by the differences in the shape of the expansion of the arterial tube. For instance, 1. True *sacciform* aneurism: 2. True *fusiform* aneurism: 3. True *cylindroid* aneurism, subdivided into that of the large arteries and into that of the small arteries, or the *aneurism by anastomosis* of John Bell, and the *erectile tumours* of Dupuytren: 4. True varix-like aneurism, or *aneurisma cyrsoideum*. In *sacciform* aneurism, the vessel has at one point of its circumference a small sac, consisting of an expansion of the arterial tunics. This variety is most frequent in the aorta, but sometimes on the carotid and iliac arteries, and even on those of the limbs. In this aneurism, all the arterial tunics are simultaneously dilated; but as the internal and middle ones have but a limited degree of extensibility, the sacciform aneurism does not generally exceed the size of a filbert, though Breschet has noticed some on the aorta as large as a hen's egg. (See *Breschet sur Différentes Espèces d'Aneurismes*, p 12, &c.)

In the *true fusiform aneurism*, the dilatation extends over the whole circumference of the vessel; all the coats participate in it. The calibre of the artery, after becoming wider and wider

gradually for a certain portion of the track of the vessel, then lessens in a manner equally gradual, till it has resumed its natural diameter.

The *cylindroid* aneurism of Breschet might be regarded only as a variety of the fusiform, inasmuch as an abrupt transition from a given calibre to a much more capacious one is never observed. Yet, according to the investigations of Breschet, cases present themselves in which the artery is uniformly dilated through a track of one or two feet, the cylindrical form being here strictly preserved. This pathological fact has been noticed by Breschet in the arteries of the limbs, and in those of the brain, and of the splanchnic cavities. (*Op.* cit., p. 25.)

In the *true varix-like aneurism*, the artery is described by Breschet as being not only dilated, but tortuous, and occasionally studded with small sacciform tumours. The parietes of the vessel are thin and collapsed, while, in the other case, they are rather thickened. Such is Breschet's classification of true aneurism; a classification which, embracing, as it does, aneurism by anastomosis and erectile tumours, and these of different kinds, presents a good deal of novelty.

CAUSES OF ANEURISM.

An aneurism will not follow the kind of weakness of its sides which must necessarily arise from removing its external and middle coat, some morbid changes seeming to be essential to bring on a protrusion of the inner coat. Neither will a mechanical division of the inner tunics lead to an aneurismal dilatation of the outer coat. The latter fact is proved by what happens when a tight ligature is placed upon an artery, as well as by the experiments of M. Amussat, who purposely broke the internal coats in numerous places by pinching the vessels with forceps, and detaching the inner coats from the outer by a process somewhat similar to what he adopts in torsion of the arteries. By proceedings of this kind, he never succeeded in producing the beginning of an aneurism. The inference therefore is, that some description of morbid change in the coats of the artery is necessary for the formation of aneurism, so long as the occurrence is resisted by a perfect state of one of those coats; or else we must arrive at the still more certain conclusion, that in the experiments undertaken by Hume, Amussat, and others, the irritation of the artery was followed by inflammation of it, coagulation of the blood, and such an effusion of fibrine within and around it as would fully account for no aneurismal tumour being the result.

One very interesting point in relation to spontaneous aneurism, and particularly adverted to by M. Malgaigne, is the almost exclusive restriction of this disease to the aortic system. Thus, in more than three hundred aneurisms observed by M. Lisfranc, or recorded by others, he has met with only two instances of an aneurismal disease of the pulmonary artery, and these not free from objection. (*Lisfranc, des diverses Méthodes, &c., pour l'Oblitération des Artères*, p. 8, 8vo, Paris, 1834.) This remarkable fact is suspected to depend upon the aortic arteries containing, between their inner and fibrous coats, a dense, hard, fragile tissue, only capable of being taken off in scales, and designated by M. Malgaigne the *sclerous* coat. When concretions of different kinds, calcareous, steatomatous, or cartilaginous, present themselves in the aorta, they are seated, according to M. Malgaigne, almost exclusively in this sclerous coat, a texture not existing in the pulmonary artery or its branches.

Both the external iliac arteries of the same individual were tied in succession by Mr. Tait, one on the 8th of May, 1825, and the other on the 16th of April; and this with entire success, notwithstanding the peritoneum was wounded in one of these operations. M. Arendt also took up both the external iliac arteries in one patient, and, though there was only an interval of a week between the operations, the case had a very favourable termination. (See *Velpeau, Nouv. Elém. de Méd. Opér.*, t. i., p. 175.)

The operation of tying the internal iliac was also performed by Mr. Thomas, of Barbadoes, who sent the preparation of the parts to Sir Astley Cooper, and it is in the Museum of Guy's Hospital. (*Med. Chir. Trans.*, vol. xvi., p. 230.) A fifth instance of the application of a ligature to the internal iliac artery took place in the practice of Mr. Hudson, of New-York.* (See *American Journ. of Med. Sciences* for Feb., 1828, art. v., p. 304.) A semilunar incision, seven inches in length, was made, with its convexity towards the ilium, from the vicinity of the umbilicus to that of the abdominal ring. After dividing the parietes of the abdomen, and tying some arteries which bled, the peritoneum was pushed upward and inward, and the handle of a scalpel passed under the trunk of the internal iliac artery, which was tied an inch below its origin. The patient recovered.

It is very justly observed by M. Velpeau, that the ligature of the internal iliac artery, with regard to its influence on the circulation, is in reality less serious than that of the external iliac, or even the femoral. In fact, it leaves undisturbed all the vessels appertaining to the corresponding limb, while the great pelvic arteries anastomose with one another so freely, that, when one is obliterated, an abundance of blood is promptly conveyed by the others to the organs which the obliterated one is designed to nourish. But the ligature of the internal iliac artery is dangerous in another point of view: first, on account of the difficulties in its performance; and, secondly, on account of the unavoidable detachment of parts from one another, which are connected together by a large quantity of loose cellular tissue, a texture in which inflammation and suppuration are disposed to spread to a great extent. (See *Velpeau, Nouv. Elém. de Méd. Oper.*, t. i., p. 185.)

On the subject of tying both carotids, I find some interesting observations made by my friend Mr. Crosse: "Although (says he) some animals will bear a ligature to both carotids simultaneously, the human frame cannot sustain so great and so sudden an interruption to the supply of blood to the sensorium. Professor Mott has tested this question; and a case came under my own observation very recently, showing the fatal tendency of a ligature, if applied almost simultaneously to each of these arteries. An approximation has, however, been made towards ascertaining the shortest interval at which the second carotid may be tied after a ligature to the first; and it has been safely done at an interval of thirty-eight, seventeen, and even twelve days. Among the most striking of these cases is that related by Professor Kuhl, of Leipzig, who, on account of a pulsating aneurismal tumour of the scalp, arising from a wound of the occiput, and extending over nearly the entire surface of the

* This should be Dr. S. P. White, of Hudson, New-York.

head, attended by frequent hemorrhages, first placed a ligature on the left common carotid. This proceeding only partially subduing the disease, and frequent hemorrhages from the affected portion of the scalp still occurring, and threatening life, a ligature was put upon the right common carotid after twenty-seven days. This was followed by convulsions; but after a train of very troublesome symptoms, the patient recovered, and was cured of his disease. It is worthy to be noticed, that in this, and also in other like cases, some days after both carotids had been tied, heaviness and throbbing in the head have occurred, requiring free venesection." (*J. Green Crosse, Prov. Med. Chir. Trans.*, vol. v.)

Guthrie has met with but three popliteal aneurisms in women; and he calculates aneurism of the ham occurs from twenty to thirty times in men for once in women. "The structure of the vessels (he observes) is the same, but the mode of life is different. The exertion in general is infinitely greater in the man than the woman; and I think this, combined with the freer use of ardent spirits, a much more likely cause than either syphilis or mercury." (*On Dis. of Arteries*, p. 87.)

In relation to the comparative frequency of aneurism in the two sexes, M. Lisfranc states that, in 154 cases, the particulars of which have been collected by him, and whose situations brought them within the reach of operative surgery, the proportion of male patients was 141; of females, 13, or nearly 11 to 1.

With respect to the comparative frequency of aneurism in different arteries, M. Lisfranc refers to 179 cases, all spontaneous, those of the aorta not entering into the computation; from which 179 cases he gives the following table:

1.	Popliteal artery	59
2.	Femoral { in the groin	26
	{ at other points	18
3.	Carotid	17
4.	Subclavian	16
5.	Axillary	14
6.	External iliac	5
7.	Brachio-cephalic	4
8.	Brachial	3
9.	Common iliac	3
10.	Anterior tibial	3
11.	Gluteal	2
12.	Internal iliac	2
13.	Temporal	2
14.	Internal carotid	1
15.	Ulnar	1
16.	Peroneal	1
17.	Radial	1
18.	Palmar arc	1.—C.]

[Dr. Valentine Mott, of New-York, has tied the common carotid artery twenty times. In two cases it was the distal operation for aneurism of the innominata, and in one of these was successful. In three instances he has thus cured aneurism by anastomosis. In two examples both of the common carotids were tied in the same patient; in the first case, the interval between the application of the two ligatures was about twenty minutes, the patient dying comatose on the second day after; in the second case, a year elapsed between the first and second operation. This case was a large aneurism by anastomosis, occupying the temporal and parotid region, originating deep about the articulation of the lower jaw. In the removal of the parotid gland, Dr. Mott found it necessary, in one case, to tie the external carotid at the point between the stylo hyoid muscle and the lingual nerve, an operation the difficulty and hazard of which every surgeon will know how to estimate. The same surgeon has repeatedly tied the external carotid near its origin in his operations for tumours.

The same surgeon has also tied the subclavian four times; once *within* the scaleni muscles of the right side, fatal from secondary hemorrhage; three times without the scaleni, all successful in curing axillary aneurisms.

Dr. Mott was the first surgeon in the world who successfully tied the common iliac artery, and this was for a huge aneurism of the external iliac near the bifurcation. Dr. Solomon, of St. Petersburgh, has since performed it with success.

This operation was performed by Dr. Mott on the fifteenth of March, 1827, and the case reported soon after in the American Journal, No. 1, p. 156. Nearly seven years afterward, the Medico-Chirurgical Review announced the successful result of the case in which Mr. Guthrie applied a ligature to the same artery, and the editor complacently observes,

"Thus this most formidable operation has been successfully performed *for the first time*, and, while it adds a wreath of laurel to the brows of the distinguished surgeon, it exhibits a splendid triumph of British surgery."

Dr. Hays, of the American Journal, in responding to this blunder of the London reviewer, reminds him that this "triumph of British surgery" belongs on this side of the Atlantic, and that he has placed the laurels on brows not destined to wear them. He then adds, "The distinguished surgeon to whom the wreath justly belongs is our colleague and countryman, Dr. Mott, who, upward of seven years since, successfully applied a ligature to the common iliac."

The British reviewer omitted, or forgot to mention, that this "*successful*" operation of Mr. Guthrie was very soon *fatal*, and he strangely fails to record the fact that the *aneurism* for which Mr. Guthrie tied the common iliac turned out to be a *malignant tumour*, which the consultation decided to be aneurism until the patient was dead, when the mistake of all parties was discovered. This record, however, would have withered the wreath of laurels upon the brow of Mr. Guthrie, and deprived British surgery of this splendid triumph.

Fifteen years have now elapsed since Dr. Mott's operation, and the gentleman is still living. And yet Mr. Guthrie himself, in his work "On the Diseases and Injuries of Arteries," p. 365, records this case of Dr. Mott as fatal, although he extracts his account of the operation from the American Journal, in which the entire restoration of the patient to health is explicitly mentioned.

Dr. Mott has also tied the external iliac six times; of these, four were successful, and two failed. The first of the fatal cases was from secondary hemorrhage, but the second died of peritonitis, from drinking to excess about a week after the operation. He also tied the internal iliac in 1834 with success, for a large aneurism in the region of the sciatic notch, and the patient is still living in perfect health.

Dr. Mott has tied the femoral artery forty-nine times, and in only one instance has secondary hemorrhage taken place. In this case the patient had a popliteal aneurism, and, after the failure of the ligature on the femoral artery, he secured the external iliac; but, on the coming away of the ligature, secondary hemorrhage

again occurred, and was ultimately fatal. This was a fair case for tying the aorta, and Dr. Mott was only deterred by the morbid state of the arterial system, as was manifest in the result of the two ligatures, which had been unsuccessful only on this account.

Dr. Mott has cured one of our citizens of a double aneurism, popliteal on one limb, and femoral on the other very high up. He tied for the former the femoral artery, and for the latter the external iliac. The patient is still living in New-York, and in entire health. The same surgeon has tied the brachial, ulnar, radial, anterior, and posterior tibial for wounds, tumours, and aneurismal diseases a great number of times with uniform success.

The left primitive iliac artery was tied for aneurism of the external iliac by Dr. Alfred C. Post, at the New-York Hospital, on the 26th of August, 1840. The case terminated fatally. An account of it is published in the New-York Journal of Medicine and Surgery, October, 1840.

Dr. George M'Clellan, of Philadelphia, has tied the common carotid artery eighteen times for aneurism and tumours. He has also successfully tied the subclavian three times, the external iliac three times, and the gluteal once.

Dr. N. R. Smith, of Baltimore, has tied the subclavian once, the external iliac once, the carotid three times, and the femoral eleven times for aneurism. The same surgeon has had occasion to tie the internal jugular vein, which he effected successfully, and the patient recovered.

Dr. Alban Goldsmith, of New-York, has tied the subclavian twice for axillary aneurism, and in one of the cases he has had entire success. He has also tied the carotid three times for aneurism by anastomoses, which was cured, and for tumours, which were afterward successfully extirpated; but he concurs in the opinion that ligating the vessel does not lessen the hemorrhage in such operations, and need never be performed.

Dr. Peace, of Philadelphia, has successfully tied the external iliac for aneurism in the Pennsylvania Hospital.

Dr. Pancoast, of Philadelphia, has had occasion several times to take up the carotid artery in cases of attempts at suicide by cutting the throat. He has observed that, in these cases, where there is much extravasation of blood to mark the parts, the descendens noni nerve is occasionally of so large a size, that its position and oblique course alone distinguish it from the par vagum.

Dr. Pancoast has devised a modified plan for the purpose of tying the subclavian artery below the clavicle, which will render the operation less difficult upon the living subject. He opens the fissure between the sternal and clavicular origin of the pectoralis major muscle, and then divides the sternal portion across, and up to the clavicle over the artery. He then turns up the divided portion, and looks for the artery beneath.

He has operated five times for aneurism at the bend of the arm by tying the brachial artery with a small ligature just below the condyle, and below where it is crossed by the median nerve, leaving the sac untouched. The cases were all recent, and the operation successful. In examples which are of long standing, he advises to open the sac and apply two ligatures.

Dr. P. has also taken up the femoral artery twice with success for popliteal aneurism. He has also tied the stylo mastoid artery for false aneurism, occasioned by bleeding. The patient was a quack doctor from the West, who oled himself, and was in the habit of bleeding his patients at the same place. The sac had burst, and profuse hemorrhage had taken place. A single ligature sufficed; but the operation must be a difficult one, when we remember the proximity of the communicating branches of the facial and great auricular nerve, which run parallel with the stylo mastoid artery opposite the lobe of the ear.

Dr. Detmold, of New-York, has recently tied the common carotid for aneurism by anastomosis, involving the whole side of the face, in a lady who was thus sadly deformed, and at the time the tumour was very rapidly increasing. Its growth was checked immediately, and the tumour is fast disappearing, so that the entire removal of the deformity will be the result.

Dr. N. R. Smith, of Baltimore, reports a case of temporary paralysis following a ligature upon the carotid artery. As this untoward result did not occur immediately, but after an interval of some twenty hours, and as it was relieved, and the patient restored by full venesection, the mischief was ascribed to the reaction in the vessels not obstructed, giving rise to vascular engorgement, and a state approaching to apoplexy, which, indeed, was indicated to be the true pathological state by the symptoms. (See *Maryland Med. and Surg. Jour. for* 1840.)

Dr. Mussey, of Cincinnati, reports a case of nævus of enormous size, situated upon the vertex, and for which he tied both of the common or primitive carotids, after an interval of twelve days. The diminution of the tumour and cessation of pulsation, which inspired a delusive hope of success, proved to be but temporary, and six weeks after he was obliged to excise the whole mass by an incision around its base, and which required forty ligatures. The patient completely recovered. (See *Amer. Jour. for* 1838.)

Dr. Horner, of Philadelphia, has published in the American Journal for 1841 an accurate and highly valuable report of two cases of aneurism, exhibiting the necessity of a ligature both above and below the tumour.

In the American Journal for 1837, Dr. Morrison, of Buenos Ayres, reports six cases of aneurism cured by operation, the details of which are honourable to this surgeon, who is a graduate of the University of Maryland, and his paper will be found to be highly interesting to the student of this branch of surgery.

Dr. T. S. Kirkbride reports, in the American Journal for 1839, five cases of wounds of arteries successfully treated by compression, illustrating the important fact that arteries are often tied for wounds and aneurisms, when compression, judiciously practised, would succeed in preventing the necessity of the operation. In this way he has thus succeeded with the radial, brachial, and femoral arteries; and, after reporting the cases, Dr. K. adds practical observations on the general subject which are of great value.

Dr. J. R. Barton, of Philadelphia, has long distinguished himself in this department of treating surgical diseases by other means than the use of the knife, justly regarding the avoidance of an operation as more meritorious than the ligation of any artery of the body. So, also, in diseased and injuries for which amputation is often practised, Dr. Barton's horror of mutilating patients has led to the employment of his engenuity and skill in preserving the limbs, even when more difficult operations than amputation are indica

ved as necessary for the purpose. Under the head of Anchylosis I have alluded to an eminent instance of his success.

In the Eclectic Repertory, vol. i., p. 506, Dr. Joseph Parish reports a case of femoral aneurism spontaneously cured. His son, Dr. Isaac Parish, relates a case of aneurism in the orbit, in the Amer. Journ. for October, 1841.

Dr. Paul F. Eve, of Georgia, has lately succeeded in curing an aneurismal varix resulting from a wound of the brachial artery, made by transfixing the vein in phlebotomy. In this case the artery was ligated above the tumour without success. Six months afterward, Dr. Eve tied the artery on the distal side of the aneurismal tumour; but this operation also failed, and the pulsation of the tumour continuing, he was led to isolating the aneurism by placing two ligatures upon it at opposite points, and by this operation the tumour was completely obliterated.

Dr. Alexander E. Hosack, of New York, has devised an instrument for tying deep-seated arteries, which practical men regard as possessing great merit. An account of it may be found in the 3d vol. of the N. Y. Med. and Phys. Journ., with a drawing. The advantage of this instrument is, that after tying the first knot, the second may be brought down without disturbing the first, as there is no stress upon the ligature between the two. It has been found to afford great facilities in ligating the internal iliac and subclavian arteries. See White's operation for gluteal aneurism, in the Amer. Journal for 1827, and also Dr. Gross's case, and remarks on the subclavian artery, Western Journal for 1841.

Dr. J. Kearney Rodgers has tied the external iliac, the internal iliac, and the femoral in the same patient, for complicated aneurisms.

Under this head I have introduced into the text the only instance of the ligature of the internal iliac for the cure of glutæal aneurism ever performed in this country, as communicated by Dr. S. Pomeroy White, of Hudson, N. Y., and it is there stated to be the fourth instance in which this operation has ever been attempted. I find, by a late number of the London Gazette, that Dr. Thompson, of Barbadoes, has since performed this difficult operation, but without success, as would seem from the fact that a preparation of the parts has been sent to Sir A. Cooper, and is now in the museum at Guy's Hospital. So that this artery has now been tied five times: twice in the West Indies, once in Russia, once in Great Britain, and once in the United States.

Dr. Stevens, of St. Croix, was the first to attempt this hazardous operation, as may be seen by a reference to the article in this Dictionary. This case occurred in 1812, and was completely successful. The patient lived ten years after the operation, and, dying in 1822 of some other disease, an opportunity was afforded of examining the parts. The preparation was sent to London to remove the skepticism of those who persevered in declaring the operation impossible. Still, however, a few distinguished men doubted the reports of the several cases, and Mr. Lawrence, in his lectures, still questioned the possibility of tying the internal iliac, and alluded to only one case in which it *was said* to have been performed. (See *London Med. Gazette*, No. 128.)

During the present year Dr. Stevens visited London in the suite of the governor-general of the Danish West India islands; and having his attention called to the skepticism of Mr. Lawrence, he immediately sent the preparation, which had been in London unnoticed for several years, to the Royal College of Surgeons, where, in the presence of Mr. Lawrence, a minute examination was made, to the entire satisfaction of all present. It appeared, however, that the aneurism was not in the glutæal artery, as had been supposed, but in the great ischiatic; and Dr. Stevens suggests that this is probably the seat of the disease, in many instances, of what has been called glutæal aneurism.

Sir Astley Cooper has given a conclusive certificate, after having minutely examined Dr. Stevens's preparation, which is also published in the Gazette, declaring himself perfectly satisfied of the existence of the aneurism, and the complete obliteration of the internal iliac. For, although this preparation has been in spirits eight years, "it still exhibits the internal iliac converted into an impervious chord where the ligature was applied, and shows very distinctly the remains of the aneurismal swelling in the ischiatic artery."

In the Western Journal of Medicine and Surgery for June, 1841, Dr. S. D. Gross, professor in the Louisville Medical Institute, reports a case of axillary aneurism for which he tied the right subclavian artery. The patient died on the thirtieth day of the effusion of the contents of the aneurismal sac into the thoracic cavity, which had obviously resulted from ulcerative absorption of the walls of the tumour, and must have commenced before the operation. But for this untoward event, entire success would have crowned the operation, for the ligature came away in due time, and the wound did well.

Dr. Gross relates the history of twenty-six cases in which this artery was tied, of which seventeen were cured. He records three instances in this country, the first by Dr. Post, of New-York, in 1817, successful; the second by Dr. Gibson, of Philadelphia, in 1828, the patient dying on the eighth day; and the third by Dr. Mott, of New-York, in 1830, in which the patient recovered. So that it appears that in America the first instance of success on record was furnished by Dr. Post; for, until his case, it had failed in the hands of Ramsden and Blizard of London, and Dr. Colles of Dublin, the only instances of this artery being previously tied. Dupuytren was the next to succeed, which he did two years after in the Hotel Dieu of Paris. The paper of Dr. Gross is an elaborate and meritorious criticism upon the whole subject, and does him great credit.

In the Eclectic Repertory, vol. iii., p. 229, Dr. Joseph Parish, of Philadelphia, has a paper on the application of a ligature to the subclavian artery, with description of instrument.—REESE.]

[ANTRUM. COLLECTIONS OF MUCUS.

In general, I believe that the extraction of one of the molar teeth will not prove very applicable to the present case; first, because the thick albuminous fluid requires a larger opening than can be thus obtained: and secondly, because, when the surgeon is called upon to perform an operation, the bony texture of the antrum is already very thin, much softened, or even partially absorbed above or behind the alveoli; consequently, as soon as the surgeon has made an incision above the gum, or in the part of the swelling presenting itself on the roof of the mouth, he finds that a probe will immediately enter the antrum. All that he has to do, therefore, is to enlarge this opening with a pair of small bone pliers or a

strong knife. Mr. Hunter's apprehension about the difficulty of maintaining the opening, and of the likelihood of a return of the accumulation, does not appear to be confirmed by what happened in the cases under Dubois and Sir Benjamin Brodie. The latter informs us that, "after dissecting the membrane of the cheek from the jaw, I took a curved scalpel, bent laterally, with a strong sharp point, and introduced the point into what seemed the thin bony parietes, or boundary of the tumour. Immediately there escaped a large quantity of transparent fluid, like what we find in cases of ranula. I then introduced a probe into the cavity of the antrum, and found that it might be passed in any direction. There was neither tumour nor dead bone in it, and the cavity seemed to be in a natural state, except that it was enormously dilated. I next enlarged the opening, cutting out a circular portion of thin bony shell, formed by the expanded parietes of the antrum. After the operation the tumour subsided, and in a few weeks the cheek was not larger than the other. The aperture made by the scalpel has continued previous to this day, though it is ten years since I performed the operation. The lady wears a plug, which she takes out night and morning, and with her own hand introduces the point of a syringe, and washes out the antrum." (See *Lond. Med. Gaz. for Dec.*, 1834.)

ABSCESSES IN THE ANTRUM.

The following way of making the opening is recommended by Sir B. Brodie: "Raise up the cheek, so as to expose the membrane covering the gum on the side of the face, and with a scalpel make a transverse incision down to the bone. In one case (says he), I did otherwise, thinking the division of the membrane, as a separate part of the operation, was unnecessary; but the consequence was, that the blood escaped into the cellular membrane underneath, and there was an immense ecchymosis, rendering the rest of the operation very difficult. Then perforate the thick plate of bone as nearly as possible to what you suppose to have been the original seat of the disease." The best instrument for this purpose, according to Sir Benjamin Brodie, is a pair of sharp-pointed strong scissors. "Apply them to the bone in their closed state, using them as a chisel, and they will easily penetrate it, and go into the antrum. With these the bone may be easily broken away to the requisite extent." (See *Méd. de l'Acad. de Chir.*, t. iv., p. 351; *Gooch's Obs., Append.*, p. 138.) Some examples occur where it is absolutely necessary to expose a great part of the surface of the bone, and to cut away the dead pieces, which are wedged, as it were, in the living ones. In general, however, it is prudent to wait till the dead bone is loose, and in the mean while to restrict our interference to preventing the lodgment of matter, and maintaining cleanliness.

TUMOURS IN THE ANTRUM.

Surgical writers describe polypi of the antrum; and as growths of this kind have their origin from parts invested by mucous membranes, it is natural to expect that the antrum would occasionally be the situation of them. Yet the disease must here be very rare; and Sir Benjamin Brodie even regards the history and treatment of polypi of the antrum as altogether hypothetical; and he adds, "No polypus, I believe, ever existed in the antrum around which a surgeon could put a ligature; and I never heard of the operation being performed." (See *Lond. Med. Gaz. for Dec.*, 1834, p. 850.) In no hospital, either civil or military, have I had an opportunity of seeing a polypus of the antrum; neither has any case presented itself to me out of an hospital. I join Sir Benjamin Brodie, therefore, in believing the disease to be exceedingly rare. There are, however, some good authorities in confirmation of the fact that polypi do sometimes grow in the antrum. (*Eichhorn, Chelius*, &c.) Certain other tumours, originating within the antrum, are far more common, some of which are of a fibrous, sarcomatous, or osteo-sarcomatous character, free from malignancy, while the others are of a malignant cancerous kind, partaking of the nature of medullary tumours, or of carcinoma, and sometimes of both these formidable diseases together. Malignant tumours are attached to the mucous membrane, and fill up the cavity. At first the patient has but little pain, and the existence of the disease is scarcely indicated by any particular symptoms. But, as the disease advances, things are different. The tumour, growing larger, presses upon the inner surface of the antrum, and causes its bony parieties to become dilated. By degrees, it forms a projection in the cheek. After a time, there is another projection in the bony palate. Then another projection occurs at the inferior part of the orbit; and there is still another blocking up the nostril. From the pressure of the tumour, the osseous texture of the antrum is absorbed; the alveoli are destroyed; and the teeth are loosened, or drop out. At length, the morbid growth either makes its way into the orbit, displacing the eye, and then passes through the orbitar plate of the frontal bone into the scull, and proves fatal, or else it protrudes through the front, or lower part of the antrum: in either of which last situations it presents a large fetid, bleeding mass, bringing the patient to his doom with equal certainty. In the Museum of London University College are three specimens of malignant disease of the antrum; in two, the swelling made its way from the antrum to the brain; in the third, which was taken from an elderly woman, a patient of mine, who died in the North London Hospital, the medullary and scirrhous mass, after entering the orbit and displacing the eye, caused ulceration and sloughing of the cheek, and a protrusion of some of the tumour in this direction. The woman, who had suffered indescribable agony from the pressure of the tumour, as it continued to enlarge, was at length worn out by the discharge, irritation, and repeated bleedings from the disease. I remember a boy in St. Bartholomew's Hospital, many years ago, in whom a medullary tumour, beginning in the antrum, made its way through the orbitar plate of the frontal bone and cribriform plate of the ethmoid into the cranium. He was only comatose about forty-eight hours before he died, though the portion of the swelling projecting into the cranium, and causing a corresponding depression in the anterior lobes of the brain, was equal in size to a small orange.—C.]

[In the article under this head, I inadvertently omitted to record a new and difficult operation performed for the removal of a fungus from that cavity, by Dr. A. H. Stevens, Professor of Surgery in the University of New-York. The details of the case are included in Dr. Stirling's Appendix to Velpeau's Surgical Anatomy, recently published. It is the more important I

should introduce it here, since in another part of this work I have attributed to Dr. Rogers the merit of having first operated in this country for the removal of the upper jaw. Dr. R.'s operation was performed, it will be perceived, in May, 1824, while that of Dr. Stevens was in August, 1823. I was led into this error, as respects the date, by the circumstance that the latter operation was not published until the present year, the doctor having withheld the report of the case from the public from motives of delicacy to the patient and his friends, lest the individual should be identified, and the extent of the mutilation known.

The tumour in this case occupied the whole antrum, arising by a broad base from its lower portion, and occasioned a great deformity in the cheek, and protruded into the mouth.

For the full account of this superior operation, I must refer to the work just mentioned. It will be sufficient here to state, that a great portion of the anterior and inferior portions of the os maxillare superius were removed *without dividing the cheek*, by drawing up the commissure of the lips, and dissecting the upper lip from the bone to within a line of the infra-orbital foramen. And the peculiar merit of the operation is in the manner of dividing the bone by a flexible elastic saw, made of clock-spring, instead of the use of the mallet, chisel, and gouges, and the still more painful and equivocal operation with the actual cautery.

This patient is now living in perfect health, and the cavity in the cheek which followed the operation has been filled by an artificial jaw, made of ivory, having teeth attached to it; and the articulation and deglutition are so perfectly retained, that only a few friends are aware of the nature of the operation to which he has submitted.

This entire triumph of our art over so horrible a disease is alike honourable to Dr. Stevens and the profession.

Professor Chapin A. Harris, of Baltimore, has reported in the Maryland Med. and Surg. Journ. for 1840, a highly interesting case of ozœna, to which I must refer the reader, as of great practical importance. It was cured by the extraction of the first superior molar tooth, the roots of which were found greatly enlarged by exostosis. This operation was found to have opened the antrum, and allowed the escape of a purulent and fœtid discharge, and indicating the proper treatment, as well as revealing the true source of the patient's sufferings. The patient was thus restored to health after being tortured by neuralgia for years.

Dr. Warren, of Boston, has reported in the Boston Med. and Surg. Journ. for 1839, a case of fungus of the antrum, of so great extent that the nostril, mouth, and orbit were opened into one common cavity by the destruction of the bony structures, and which required the removal of the upper jaw, including the malar bone. The patient speedily recovered this formidable mutilation, so creditable to the surgeon who thus rescued him from a horrible death. See Dr. Warren's work on Tumours, and article Jawbone.—Reese.]

[ANUS. PROLAPSUS ANI.

In the treatment of a child, Sir Benjamin Brodie recommends occasional purging with calomel and rhubarb; the avoidance of much vegetable food, which tends to fill up the intestines, while it affords but little nourishment; and an injection, every morning, of two or three ounces of a lotion, compound ʒj. of tinct. ferri muriatis, and a pint of water. The child is to retain the injection as long as possible. Sir Benjamin Brodie has never seen a prolapsus of the rectum in a child which was not cured in this manner.

ARTIFICIAL ANUS.

The following general directions were given by Dupuytren for the application of his *enterotome:* 1. The two ends of the bowel must be detected. 2. The septum between them divided. 3. The external opening healed up.

The lower end of the intestine he frequently found very difficult to make out. In old cases, very often neither the angle (éperon) nor the lower portion of the bowel can be discovered; and it seems as if there was only one passage leading to the fistula. The other, partly obliterated and retracted within the belly, has an orifice so concealed, that, unless accidentally entered by a probe, its detection is almost impossible. Then the relation of the two portions of intestines to one another Dupuytren found remarkably inconstant. The stomachic portion, according to the kind of case, may be superior or inferior, external or internal. When the artificial anus communicates with the great intestine, he considers clysters among the best means of discovering the orifice of the lower continuation of the intestinal canal. In very difficult cases, he sanctions the use of a plug, purgative clysters, and a very full diet. (See *Clinique Chir.*, t. ii., p. 265.)

The two ends of the bowel being ascertained, the operation must not be performed if the mucous coat of the bowels, the peritoneum, or other organs be the seat of acute or chronic inflammation. The patient is to be prepared by a suitable, mild, antiphlogistic plan.

In the operation the patient is to lie upon his back. The surgeon takes one of the branches of the *enterotome* in the right hand, and guides it, if requisite, with the left forefinger to one of the orifices of the bowel to the depth of one, two, three, or four inches, according to circumstances. An assistant then takes charge of this first part of the instrument. The other branch is then introduced into the other end of the bowel in the same manner. Both branches are then brought together, and joined like a pair of forceps. The blades are then made to grasp the bowel by pressing the handles together. The pressure is next regulated and maintained by means of a screw. Before the expiration of the first day, the pressure is to be increased sufficiently to kill the portion of intestinal tunics embraced by the instrument; and the pressure is to be again augmented every second day, to render their destruction still more certain. In the cases under Dupuytren, the instrument was detached between the seventh and tenth day, bringing away with it the destroying jutting angle and septum, which prevented the upper portion of bowel from communicating with the lower. Frequently the first signs of the re-establishment of the natural passage precede the detachment of the enterotome. In all cases slight colic occurs; the evacuations are at first white and albuminous from the lower bowels, and these are followed by stercoraceous matter from the upper ones. At first they are numerous and liquid, and attended with gripings; but they soon become of proper quality, and all uneasiness subsides. (See *Dupuytren* in *Clin. Chir.*, t. ii., p. 264, &c.)

FISSURES OF THE ANUS,

As they are termed, consist of longish superficial ulcerations near the anus, between the converging folds of the fine skin and mucous membrane. When the sides of the anus are separated, and the patient is desired to strain, a narrow fissure is seen, the bottom of which is red, and the margins somewhat swollen and callous. But, as Dupuytren observes, it is frequently necessary, for the purpose of ascertaining how high it reaches, to introduce the finger into the rectum. It is more commonly situated at the sides and back of the anus, than at the forepart of it; a favourable circumstance in relation to an operation, particularly in women, in whom this opening is divided from the posterior commissure of the vulva only by a thin partition. The ulceration rarely effects the whole thickness of the mucous membrane. (See *Dupuytren, Clinique Chir.*, t. iii., p. 283.) Fissure of the anus is usually productive of violent lancinating or burning pain, which gradually augments, and lasts a considerable time after the patient has had a motion. In some cases, indeed, so extreme is the suffering, that the patient, from a dread of obeying the call of nature, refuses, as long as possible, or even nearly starves himself, to render the occasion for emptying the rectum less frequent. The severity of the case arises chiefly from a painful spasm of the sphincter muscles.

Constipation, and the spasm which it excites, are among the predisposing causes of fissure of the anus. The indurated fecal matter, either by causing ulceration of the mucous membrane, or by immoderate distention of the passage, may bring on the complaint. The unskilful administration of clysters, especially with pointed rough pipes, is often the cause. Fissures of the anus are frequently met with in persons who have piles; and, according to Dupuytren, the lodgment of venereal matter near the anus, as happens in many women, may lead to the complaint. Perhaps it would be more correct to say that the contact of any irritating matter or secretion may have this effect.

According to Dupuytren, the spasmodic constriction of the sphincter is the real disorder, and the fissure is only a secondary effect. By putting a stop to this constriction, the disease is cured. With this view, Dupuytren tried what good could be done by the following application: ℞. Axungiæ ʒ vj., extr. belladonnæ plumbi acetatis ā ā ʒ j. Misc. A tent of linen or charpie, or, as I should say, a soft rectum bougie, of moderate size, smeared with this ointment, is introduced, and its diameter gradually increased to that of the forefinger. Dupuytren states that the continuance of this treatment for a few days frequently relieves the pain entirely, and obviates all necessity either for caustic or the division of the sphincter. Even when the plan does not cure, it always palliates, and therefore should be tried before the latter methods are resorted to.

Baron Dupuytren makes a very useful and practical division of fissures of the anus into three kinds. *Some are below the sphincter*, affecting hardly any texture but the skin, and not the mucous membrane. These excite more or less pruritus, but cause little obstruction to the passage of the feces. *Fissures above the sphincter*, involving the mucous membrane, can only be seen with the aid of a speculum. When the finger is passed into the rectum, a knotty, hard chord is felt, and pressure on it creates acute pain. When the patient goes to stool, such fissures give rise to an indescribable sort of tenesmus, which ceases directly after the evacuation; and the excrement on the side nearest the disease is covered with puriform or mucous, bloody fluid. Such fissures were found by Dupuytren to be commonly produced by the ulceration of internal piles, excited by the passage of indurated fecal matter. Lastly, fissures on a *level with the sphincter*, are the worst, being attended with agonizing constriction of the sphincter, and other symptoms already specified.

The first two descriptions of fissure may mostly be cured without any operation; some by the dressing them with simple cerate, or ointment containing opium, mercurial preparations, &c.; others by emollient anodyne lotions or applications. But when the fissure was of the third description, Dupuytren considered the operation first introduced by Boyer the quickest and surest means of cure. This consists in dividing the anus and sphincter with a probe-pointed bistoury, passed into the rectum, and cutting directly through the fissure, except when it lies forward towards the vagina in the female, or urethra in the male subject. When several fissures existed, Dupuytren sometimes made several cuts in different directions, from three to four lines deep. (See *Clin. Chir.*, t. iii., art. 10.)

PRETERNATURAL CONTRACTION OF THE SPHINCTER.

Sir Benjamin Brodie has treated of this as a distinct affection; and, indeed, we find that Dupuytren represents it as being generally the primary complaint in fissure of the anus. The cases referred to by the former gentleman he has met with chiefly in women disposed to hysteria, though sometimes in the male sex. In emptying the rectum, the patient is obliged to strain very much, especially when the feces are solid; then pain is experienced, which lasts a considerable time afterward. Very often a small ulcer of the mucous membrane of the rectum (the second variety of Dupuytren's fissure) accompanies spasmodic contraction of the sphincter, and is always, according to Sir Benjamin Brodie's description, situated at the posterior part, opposite the point of the os coccygis. When the suffering is not excessive, relief may sometimes be derived from purgatives, given to prevent the evacuations from being hard and figured, from an opiate suppository at night, and from the introduction of a bougie into the anus just before the patient has a motion. In worse cases, Sir Benjamin Brodie recommends the division of the sphincter with a straight probe-pointed bistoury. The fibres of this muscle are thick, and will require two or three strokes for their complete division. An opiate may be given to keep the bowels quiet for two or three days afterward; then a dose of castor oil may be exhibited. Simple dressings will suffice to heal the wound. (See *Brodie in Lond. Med. Gaz.* for 1834, 1835, p. 26.)

EXCRESCENCES OF THE ANUS.

These cases are frequent, the growths receiving a variety of names, according to their supposed resemblance to things, as condylomata, mariscæ, and fici. Some are much firmer than others; some of them grow in consequence of irritation of the skin of the anus, by the contact of rancid secretions or purulent matter. Others are originally piles, for, as Sir Benjamin Brodie observes, when the cavities of external piles be

come obliterated, they generally form flaps of skin, which gradually waste; but sometimes diseased action takes place in them, and they become converted into excrescences similar to those which grow from the nymphæ of women. Many excrescences about the anus and perineum are of middling consistence, between that of a wart and that of a polypus. I have cured a great number by stimulating applications, as the nitrate of silver, the tinc. ferri mur., the acetic acid, and the powder of savine, blended with subacetate of copper, or a solution of the sulphate of copper. When their necks have been narrow, I have also extirpated many of them with ligatures. But, in general, I remove the larger kinds with a bistoury. The bleeding, which may be at first copious, does not generally require a ligature, as it stops as soon as lint or linen dipped in cold water and a T bandage have been applied. (See HEMORRHOIDS and RECTUM.)—C.]

[Dr. J. C. Warren, of Boston, has cured twelve cases of fissure of the anus. In three of them he relied upon laxative medicines and the local application of the nitras argenti, but in nine of them he found it necessary to divide the sphincter with the knife.

The late Dr. George Bushe, of New-York, published in 1837 a treatise on the malformations, injuries, and diseases of the rectum and anus, which will be found to possess very great practical value. It is comprised in some three hundred octavo pages, and accompanied by nine quarto plates.

In Professor Gibson's late work on the Institutes and Practice of Surgery, vol. ii., p. 140, a just encomium will be found upon Dr. Physick, of Philadelphia, for his ingenious and successful operation for artificial anus devised by him in 1808, and afterward imitated, with similar success, by Dupuytren of Paris. The claims of Dr. Physick to priority in this surgical achievement are fully sustained by Dr. Gibson, by an extract from Dr. B. H. Coates's able paper on the subject, published in the N. A. Med. and Surg. Jour., vol. ii., p. 269.

Dr. J. R. Lotz, of New-Berlin, Pa., has successfully operated by a method which he considers an improvement on both Physick and Dupuytren. (See *Amer. Journal*, No. 36, p. 367.)—REESE.]

[AORTA. COMPRESSION OF THE AORTA,

In order to restrain hemorrhage from the inferior half of the body, more especially from the uterus, has been warmly advocated, and in thin persons seems calculated to be beneficial. (See *Crosse, Provincial Med. and Surg. Trans.*, vol. v.) I have mentioned the adoption of this plan by Sir Astley Cooper, in the case where he opened the aneurismal sac previously to putting a ligature on the aorta.—C.]

[ARSENIC. Dupuytren was in the habit of employing certain preparations of arsenic, which cleaned the diseased surfaces without destroying them. One of his formulæ was a powder, the other a liquid. The arsenious acid constituted the basis of both. The calomel, joined with it, he conceived might have some effect; but the arsenic was the essential thing. The powder consisted of four parts of arsenious acid or oxide of arsenic, and ninety-six of calomel. Sometimes the proportion of arsenic was increased to five or six parts in the hundred. The liquid preparation was principally the above powder mixed with gum arabic, and moistened with distilled water, so as to make a paste. In the latter formula, however, Dupuytren usually increased the proportion of arsenic, employing six, eight, ten, or twelve parts of arsenic with so many parts of colomel as made, with the arsenic, one hundred. Dupuytren employed this application with considerable success for the cure of many phagedenic ulcerations of the lips, and other parts of the face, approaching almost to cancer in respect to obstinacy. (See *Clinique Chir.*, t. iv., p. 471.) In the North London Hospital I employed Dupuytren's arsenical powder last year, in one or two instances of the same kind, with complete success. In lupus, or noli-me-tangere, it is a valuable application.

If the pump be used, Dr. A. T. Thomson is of opinion that lime-water should be used to wash out the stomach. The union of lime and arsenious acid forms a nearly insoluble salt; so that, while we are freeing the stomach from its deleterious contents, we are also lessening the virulence of any part of it which may remain. If the above emetics be given, lime-water should be drunk immediately after the first act of vomiting. Oil, and also milk, may be given, but no diluent fluid calculated to dilute and dissolve the arsenious acid. Alkaline solutions are objectionable, because the alkaline arsenites are very soluble, and as poisonous as arsenic itself. (See *Thomson's Elements of Therapeutics and Materia Med.*, p. 518, ed. 2.)

In 1834, the peroxide or hydrated tritoxide of iron was discovered by Dr. Bunsen to be a powerful antidote if administered in time. (See *J. G. Crosse* in *Prov. Med. Trans.*, vol. v., page 51; *J. Robson* in *Lond. Med. Gaz.*, Nov. 5, 1836.)—C.]

[ARTERIES. In the article Aneurism I noticed the questions about the propriety and safety of tying both carotids, and whether this could be done without extraordinary risk when no interval was left between the two operations. With respect to these points, I find that M. Manec is decidedly of opinion that both the common carotid arteries may be tied at once in the same individual, without any marked or lasting derangement in the functions of different parts of the head. He believes that the numerous anastomoses which exist in the interior of the scull, between the terminating branches of the vertebral arteries and those of the internal carotid, are more than sufficient for the ready conveyance of blood from the former into the latter, and for the prevention of the brain from being sensibly affected by the obliteration of the two common carotids. Externally, the numerous communications between the branches of the external carotids and those of the two subclavian arteries, more particularly the free anastomosis of the lower thyroid with the superior thyroid arteries, and those of the ascending cervical with the occipital arteries, leave no doubt in M. Manec's mind respecting the correctness of the opinion which he has advanced. He has frequently tied both the common carotids in animals without the slightest impairment of their intelligence or of their general health. At the period when he was recording his views of this subject, there was in the dissecting-room of the hospital a large, strong, healthy dog, on which he had performed this operation four years previously, and whose intelligence continued perfectly undiminished. So fully convinced is M. Manec of the safety with which it may also be practised on the human subject, that he wished to undertake it on a young man who had an ex-

tensive tumour of erectile tissue on the face, but who would not submit to the proposal. (See *Manec, Traité, &c., de la Lig. des Artères*, pl. iv.)

Perhaps, in no operation of tying an artery, is the exclusion of the veins and nerves of so much consequence as it is in that of applying a *ligature to the common carotid artery*. As Dupuytren remarks, this fact depends upon the importance of the organs to which the adjacent nerves are distributed, viz., the heart, lungs, and stomach. (See *Leçons Orales, &c.*, t. iv., p. 17.)

The right common carotid trunk is much shorter than the left; the former arising from the brachio-cephalic trunk, the latter from the arch of the aorta. Both terminate opposite the space between the os hyoides and upper edge of the thyroid cartilage; and behind each of them are the longus colli and rectus capitis anticus muscles, placed in front of the cervical vertebræ. In the lower part of the neck, the trachea is near their inner side; higher up, the thyroid gland; and still higher up, the larynx and pharynx. The external side of the common carotid is in contact with the internal jugular vein, which partly overlaps it; while between the two vessels, but rather behind them, and enclosed in the same common sheath with them, the pneumogastric nerve descends. In the lower part of the neck, the carotid sheath has behind it the recurrent laryngeal nerve and the inferior thyroid artery. The descending branch of the ninth nerve commonly lies upon the forepart of the sheath, closely connected to it, and about the middle of the neck forms a plexus with some filaments from the second and third cervical nerves. At the upper part of the neck it lies rather towards the outer side of the sheath; at the lower, on the inner side of it. Mr. Harrison has often found it within the sheath, behind the jugular vein. The sympathetic and cardiac nerves are situated between the sheath and the rectus anticus major muscle. The common carotid artery is covered below by the skin, platysma, and cervical fascia, and also by the sterno-mastoid, sterno-hyoid, and sterno-thyroid muscles. Opposite the upper rings of the trachea it is crossed by the omohyoideus, but from this point to its bifurcation the vessel is covered only by the skin, platysma, and fascia. The omohyoideus, as it proceeds from the shoulder behind the sterno-mastoid muscle, divides the artery into an upper and lower portion, and the side of the neck into two triangular spaces. In the lower triangle, bounded by the trachea, clavicle, and omohyoideus itself, the common carotid is concealed by the sternal origin of the mastoid muscle, and lies deeply; but in the upper triangle, bounded externally by the margin of the sterno-mastoid muscle, above by a transverse line, denoting the uppermost extent of this space below the os hyoides, and below by the omohyoideus, the vessel is much more superficial. Here, however, a plexus of veins often lies directly in front of the carotid sheath. (See *Velpeau, Nouv. Elém. de Méd. Opér.*, t. i., p. 234; *Quain's Anatomy*, ed. 2, p. 437; *Harrison's Anat. of Arteries*, vol. i., p. 19, ed. 2; *Manec, Traité de la Lig. des Artères*, No. i., pl. iv.) A chain of absorbent glands lie near the carotid sheath, principally on its external side, and are partly concealed by the sterno-mastoid muscle, and covered by the cervical fascia. In young subjects they are large and numerous; "they are frequently enlarged and indurated by chronic inflammation; the muscles and fascia press them closely to the vessels; they become fixed, and have a pulsation communicated to them, so as to resemble aneurism." (*Harrison, Op.*, vol. cit., p. 21.)

The operation of tying the common carotid is sometimes performed while the patient is in the sitting posture; but, on account of the chance of his becoming faint, I consider the recumbent position best, with the chest somewhat raised, the neck moderately extended, and the chin turned towards the opposite side. If the artery is to be tied below the omohyoideus, the front edge of the sterno-mastoid muscle is to be first felt for, and an incision, three inches long, made in the direction of it, commencing opposite the cricoid cartilage, and directed towards the sterno-clavicular articulation, a little above which it is to terminate. On the other hand, when the artery is to be taken up above the omohyoideus, the incision through the skin should begin higher up, and not be continued so low down. The second stroke of the knife divides the platysma myoides and cervical fascia so as to bring into view the fibres of the sterno-mastoid muscle. Unless this last incision be made over the latter muscle, it is best to pinch up a portion of the cervical fascia with the forceps, and cut it across, so as to make a small opening in it for the introduction of a director, on which it is to be slit up. (See *Quain's Anatomy*, p. 450, ed. 2.) An assistant now draws the inner margin of the wound, and the sterno-thyroid and sterno-hyoid muscles, towards the median line, while the surgeon himself draws the external margin of the wound and the sterno-mastoid muscle outward. For this purpose, blunt hooks are sometimes preferred, as not concealing the parts so much as the fingers.

The *omohyoideus* is now seen running across the wound in the form of a red cord, and above and below it are the vein and artery, enclosed in their common sheath.

This sheath should be opened over the artery, and not over the vein, with the aid of a pair of forceps and a director. If the jugular vein swell up so much as to conceal the parts, pressure is to be made on it at the upper angle of the wound. (See *Velpeau, Nouv. Elém., &c.*, t. i., p. 241.) Then an eye-probe or aneurism-needle is to be conveyed between the vein and artery, and under the posterior surface of the latter, without meddling with the pneumogastric nerve, the great sympathetic, or any of their branches.

It seems to M. Velpeau, that if the surgeon were to cut at first to the inner side of the mastoid muscle, there would be some risk of mistaking the sterno-hyoideus for it, and getting wrong. He thinks it better, therefore, to cut down upon the surface of the sterno-mastoid muscle, a few lines from its anterior margin. As the coats of the vein are very thin and easily torn, the knife is never to be applied near it.

If the sheath were not duly opened, the pneumogastric nerve, situated within its posterior layers, between the carotid and jugular vein, would certainly be tied, and the cardiac nerves and descendens noni be in danger of suffering the same fate.

The ligature of the common carotid above the omohyoideus is rendered easier by the more superficial situation of the vessel, which is merely covered by the skin, platysma, and the cervical fascia. The incision is to commence a little below the angle of the jaw, and be continued down to the extent of about three inches in the upper triangle of the neck, that is, in the interspace

between the sterno-mastoid muscle and the larynx. The skin and platysma having been divided, the cervical fascia is to be pinched up with a pair of forceps, and an opening made in it by cutting it across. Then a director is to be introduced, and the operation finished according to the directions already given as applicable to that below the omohyoideus.

In the operation of applying a *ligature to the subclavian artery, on the outside of the scalenus anticus*, the patient is to lie on his back, with his shoulders somewhat raised. The head and neck are to be turned towards the sound side, while an assistant depresses the shoulder, and raises the arm from the side. The first incision is to be made transversely, an inch above the clavicle, as Velpeau prefers, or near, or even upon, as many other surgeons prefer, from the outer edge of the sterno-mastoid muscle to the front edge of the trapezius. After the integuments have been cut, the platysma myoides is to be divided. The external jugular vein itself may generally be drawn aside with a blunt hook; but, if this cannot be readily done, a double ligature must be put under the vein, and tied, after which it is to be cut through in the interspace. Then the cervical fascia is soon exposed, which is to be cautiously opened by pinching a piece of it up with the forceps, and making a small opening, which is to be enlarged with the aid of a director. The edge of the scalenus anticus can then be immediately felt under and within the sterno-mastoid muscle. After having lacerated or separated the cellular tissue, absorbent glands, &c., in the bottom of the wound, with a probe or a director, the finger is conveyed towards the insertion of the scalenus, where the tubercle of the first rib will be felt, a little behind and on the outside of which the artery is always situated.

When once the artery is found, it is not necessary to bring it into view; for the nail, being applied to its posterior and external side, serves as a guide for the bent eyeprobe or aneurism-needle, the point of which is to be passed from before backward, and a little from without inward, the surgeon keeping his finger over the artery, between it and the lowermost nerve of the brachial plexus, so as to steady the vessel. (See *Velpeau, Nov. Élém.*, &c., t. i., p. 229.)

With reference to the *ligature of the external iliac artery*, I have but little to add to the account given of this subject in the article Aneurism. From the sacro-iliac symphysis, where the common iliac artery bifurcates, down to the crural arch, the external iliac artery describes a gentle curve, which is more marked in the female than the male subject, and the convexity of which is turned outward and backward. The artery descends along the inner margin of the psoas muscle, to which it is connected by a thin membrane, derived from the iliac fascia, situated behind the artery. Although the production from the iliac fascia is so thin that the artery and vein can be seen through it, yet it is sufficiently strong to prevent them from being displaced or separated. (See *Harrison's Surgical Anat. of the Arteries*, vol. ii., p. 117.) The vein lies to the inner side of the artery, and at first rather behind it; but, near Poupart's ligament, it is on the same plane as the artery, resting upon the os pubis, and upon a few fibres of the psoas and pectinæus muscles. The anterior crural nerve is on the iliac side of the artery, but on a plane posterior to it, and separated from it by the psoas, between which and the iliacus internus the nerve covered by the iliac fascia is imbedded. "Two or three small branches from this nerve, and from the lumbar plexus, are connected to the artery, and descend along its external side. These branches are distributed to the spermatic cord and to the integuments of the groin." (See *Harrison, Op.* cit.) The ureter, in its descent behind the peritoneum, crosses over the anterior surface of the external iliac artery, and so does the vas deferens. As for the peritoneum, it is connected to the external iliac artery merely by loose cellular tissue, and below quits the vessel entirely to be reflected over the posterior surface of the parietes of the abdomen. The only branches of importance which the external iliac artery gives off are the circumflexa ilii and the epigastric, which usually arise opposite the ilio-pectineal line, though sometimes a quarter or half an inch above or below this point. The absorbent glands, which lie in the course of the external iliac artery, being sometimes enlarged, excite a suspicion of diseases which do not exist. On the right side, the cœcum, and on the left, the sigmoid flexure of the colon, are the only viscera interposed between the external iliac artery and the parietes of the abdomen. As MM. Bogros and Velpeau have noticed, nothing is easier, in a thin person whose abdominal muscles are relaxed, than to make effectual pressure on this artery. M. Velpeau had an opportunity of ascertaining the truth of this observation in a young man, who met with an accidental wound of the artery above the origin of the epigastric, requiring the injured vessel to be tied without delay. (See *Velpeau, Nouv. Élém. de Méd. Opér.*, t. i., p. 172.)

In Abernethy's method of tying the external iliac artery, an incision is made, about three inches and a half in length, in the direction of the artery, down to Poupart's ligament. The aponeurosis of the external oblique muscle being thus exposed, is to have an opening cautiously made in it; and, a director being now introduced, the aperture is enlarged in the direction, and to the same extent, as the wound in the integuments. "The internal oblique and transverse muscles, which are closely connected with each other, are to be carefully cut into the lower part, so as to allow a director, or the point of a finger, to be introduced below them, when they also are to be divided, the finger separating them from the fascia transversalis and peritoneum. The fascia transversalis, running from Poupart's ligament to the peritoneum, is now to be torn through with the nail, immediately over the pulsating artery, and the peritoneum is to be separated by the finger, and pushed upward until sufficient room is obtained, which, in this, as well as in all other operations on the iliac arteries, is sometimes difficult, on account of the protrusion of the intestines, covered by the peritoneum, when the patient is not sufficiently tranquil. The artery is yet at some depth, and covered by a dense cellular membrane, connecting it to the vein on its inside, and which must be torn through with the nail. The aneurism-needle should be passed between the vein and the artery, and the point made to appear on the outside of the artery." (See *Guthrie on Dis., &c., of the Arteries*, p. 373.) This description, with the observations in the article Aneurism, will suffice to render Abernethy's plan very intelligible.

To the account of Sir Astley Cooper's method of taking up the external iliac artery, given in that part of the Dictionary, I have nothing to add

In the article Aneurism, a description is given of the operation of *tying the femoral artery* in the upper third of its course. If it were indispensable to apply a ligature to it in the *groin*, or *just below the crural arch*, the surgeon should remember that here the situation of the artery corresponds to the mid point between the anterior superior spinous process of the ilium and the tuberosity of the os pubis; though in women, in whom the pelvis is wider, the artery is rather nearer the pubes. The vessel may also be readily felt as it is passing over the os pubis, being only covered by the integuments, superficial fascia, some lymphatic glands, and the fascia lata. Immediately below Poupart's ligament, the femoral vein lies on the pubic side of the artery. The anterior crural nerve lies about half an inch away from the iliac side of the artery, imbedded between the iliac and psoas muscles. (See *Harrison's Surg. Anat. of Art.*, vol. ii., p. 136.) Here the sartorius is completely to the outer side of the artery, not interfering in any way with its exposure, nor serving as a direct guide to it, as it does in the middle third of the thigh. In the operation, the limb should be extended and rotated outward; an incision made, beginning about an inch above Poupart's ligament, and extended downward, in the direction of the artery, to the distance of two inches below this ligament. The layers of the superficial fascia are then to be divided to the same extent, and any lymphatic gland in the way pushed to one side, or, if enlarged and diseased, removed. The fascia lata is next to be divided, and the sheath of the femoral vessels pinched up with a pair of forceps, and cautiously opened. Lastly, the aneurism-needle, or eye-probe used for the conveyance of the ligature under the artery, is to be introduced on the pubic side of this vessel, between it and the vein, so as to leave the latter completely safe. As, in some individuals, the origin of the profunda is unusually high up, and of nearly the same size as the femoral, one of them might be mistaken for the other. The profunda, however, is the more external of the two. The effect of pressure on each in checking the hemorrhage, or the pulsation of an aneurism, will also be a guide to the operator. (See *Harrison, Op.*, vol. cit., p. 160.) Sometimes a double femoral artery has been met with.

The direction given by M. Malgaigne, to place the ligature as closely as possible above the origin of the profunda (*Man. de Méd. Opér.*, p. 188), if adopted, would be very likely to be followed by secondary hemorrhage, for reasons elsewhere explained. (See HEMORRHAGE.)

The operation of *tying the femoral artery in the middle third of the thigh* not having been fully described in the article Aneurism, I annex the following particulars: This artery, in its course from the crural arch to the lower third of the thigh, runs in the direction of a line, which, drawn from the centre of Poupart's ligament, descends obliquely inward round the limb to the middle of the popliteal space. This description is nearly correct; but, as Dr. Quain observes, as this line runs along the inner surface of the thigh, its course is more oblique than that of the vessel, which is placed much nearer the shaft of the femur. (See *Elem. of Anat.*, p. 505, ed. 2.) In the middle third of the thigh the femoral artery is more deeply placed than in the upper, because, in addition to the integuments, superficial fascia, and fascia lata, it has the sartorious lying over it, beneath which there is also another fascia extended over it, from the adductor muscle to the vastus internus. This fascia, though thin above, becomes very dense where the artery approaches the opening in the adductor magnus. In the groin the femoral vein lies close to the inner side of the artery, but as it descends it gets more under the latter vessel, and in the popliteal space it is situated quite to the outer side of it.

An incision three inches in length is to be made along the inner edge of the sartorius, which is the common rule, and perhaps better than Lisfranc's modification, which consists in making an incision of this length in the mid space between the gracilis and sartorius; for, by exposing the fibres of the latter muscle, their very course affords useful instruction to the surgeon; for he then knows immediately where he is, and what ought to be done. The integuments and superficial fascia having been divided, and the fascia lata to the same extent, the inner edge of the sartorious is exposed. This is to be gently raised and drawn outward. The fascia, extending from the vastus internus to the adductor, and covering the artery, is brought into view, and, with the aid of a pair of forceps and a director, it is to be cautiously opened, by which means the sheath of the femoral vessels will be exposed. Here the great saphænal nerve lies within the sheath, on the anterior and external side of the artery, and the rule is not to include it in the ligature. Lastly, the aneurism-needle is to be conveyed under the artery, between it and the vein. In making the incision through the integuments, the great saphænal vein should be avoided by not directing the knife too obliquely downward and backward.

In addition to what has been stated in the article Aneurism respecting the *ligature of the brachial artery*, I may observe, that the course of this vessel corresponds to an oblique line drawn from the armpit to the middle of the bend of the elbow. The median nerve, which above runs along its radial margin, soon gets in front of it, and, crossing it very obliquely, passes quite to its ulnar side below. Two satellite veins usually accompany the artery, and even sometimes cover it, and thus separate it from the median nerve. The ulnar and internal cutaneous nerves, which lie near it above, separate farther and farther from it as they descend, in order to reach the inner part of the forearm. The artery, lying at first near the humerus, between the coraco-brachialis and the tendon of the latissimus dorsi, afterward passes over the insertion of the coraco-brachialis, and gets upon the brachialis anticus, a little behind the inner margin of the biceps, which last muscles it accompanies to its termination. In the supine state of the hand the brachial artery is less covered by the biceps; and hence, in the operation of taking it up, this position is advantageous. (See *Manec, Man. de Méd. Opér.*, p. 166.) In thin subjects the fascia is almost contiguous to it, and sends off a duplicature to include the artery, its two accompanying veins, and the median nerve, all which form, as it were, one common fasciculus.

The whole is covered by the common integuments, and, in the lower third of the arm, by the trunk of the basilic vein. The anomalies of the brachial artery are very frequent. Velpeau and most other surgeons have seen it divide near the axilla, and at nearly every other point between this and the elbow. In one subject Velpeau found its bifurcation take place two inches above the trochlea of the humerus, to form the ulnar

and posterior interosseous. In another, the latter was completely independent of both the ulnar and the radial. Sometimes the two trunks produced by the bifurcation pass down to the forearm parallel to one another; in other instances they cross once, or several times; and it is not uncommon to find one piercing the fascia so as to get immediately under the skin, while the other, which then gives off the radial and the interosseous, retains its ordinary relations. (See *Velpeau, Nouv. Elém. de Méd. Opér.*, t. i., p. 210.)

In the operation of *placing a ligature on the brachial artery at the bend of the elbow*, the surgeon should remember that the course of the vessel here corresponds to a line drawn obliquely inward and upward, from the middle of the front of the elbow to the inner border of the biceps. Its course is also denoted by the median basilic vein, which passes under the skin almost in the same line as the artery. An incision, between two and three inches in length, is to be made through the skin on the inner side of this vein, which is to be carefully drawn out of the way. Then, with the aid of a director, the fascia, and the fibrous production given off from the tendon of the biceps, are to be divided, which having been accomplished, the artery will present itself, bounded on the right and left by its two venæ sodales, the median nerve lying three or four lines from its inner border. To facilitate the passage of the aneurism-needle or director under the artery, the elbow is to be a little bent, and the instrument passed from within outward under the vessel. (See *Manec, Op.* cit., p. 166.) If the operation were performed somewhat higher, the surgeon must remember, that two or three inches above the trochlea of the humerus the median nerve would begin to be in front of the artery.

In the *upper part of the arm*, the brachial artery lies at the inner border of the coraco-brachialis, and has the median nerve at first external to it, and then in front of it. Below the insertion of the coraco-brachialis, it is situated at the inner edge of the biceps. Four circumstances are enumerated as guides for the external incision: 1. The inner edge of the coraco-brachialis above, and that of the biceps below. 2. A line drawn from the middle of the axilla to the middle of the bend of the elbow. 3. Placing the fingers on the median nerve, and cutting on its inner side. (*Lisfranc.*) 4. The pulsations of the artery. The knife is carried in the direction of the artery from above downward in the right arm, and from below upward in the left, and an incision made in the integuments about three inches long.

With the forefinger the surgeon next endeavours to feel the median nerve, which presents itself as a round very hard cord, and to distinguish the artery by its pulsations. He then divides, with the aid of a director, one after the other, the fascia, and the sheath given off by it to the median nerve; and breaking, with the end of a probe or director, the fibro-cellular covering of the vessels, separates the artery from the veins, and puts a ligature under it. Except when anomalies occur, the operation is simple. M. Velpeau has only once seen the median nerve under the artery. In all ordinary cases it is the first cord met with behind the inner margin of the biceps. (See *Velpeau, Nouv. Elém., &c.*, t. i., p. 211.)

As some very celebrated surgeons have made the serious mistake of tying the median nerve for the brachial artery, I advise the practitioner never to tighten the ligature until he has tried the effect of pressure on what he supposes to be the artery.

In order not to mistake the ulnar for the median nerve, and to be led to seek for the artery where it will not be found, it is an excellent rule to proceed in the operation from the anterior to the posterior part of the arm. (See *Manec, Man. de Méd. Opér.*, p. 167.)

Ligature of the Radial Artery behind the Carpus.—If the thumb be forcibly extended, the tendons of its great abductor and long extensor will be made very prominent behind. In the depression between them, the pulsations of the radial artery can be felt. The thumb being drawn away from the forefinger, an incision an inch and a half in length is to be made in the direction of the foregoing tendons, first through the skin, and then through the fascia. The artery is then to be separated from some veins and nervous filaments with a probe or director. (See *Manec, Op.* cit., p. 163.)

After the radial artery leaves the forepart of the wrist, it may be taken up by making an incision "on the outside of the insertion of the extensor primi, internodii pollicis, and the inside of the extensor tertii internodii pollicis. Between these tendons the artery lies very deep, and over it is the extreme branch of the muscular spiral nerve. We find the artery going close to the notch, between the os scaphoides and trapezium." (*Sir C. Bell, Op. Surgery*, vol. ii., p. 373.)

Ligature of the Radial Artery in the Lower Third of the Forearm.—Here the artery can readily be felt, being only covered by the fascia and the skin. On each side of it is a vein; but the radial nerve is considerably to the outer side of it, having passed under the supinator radii longus a little below the middle of the forearm. An incision two inches and a half long is to be made a little way from the radial margin of the flexor carpi radialis, between this and the supinator longus. The fascia is to be opened, and the ligature passed from within outward, or from without inward, as the surgeon may choose, as it is a matter of indifference, the nerve being out of danger.

Ligature of the Radial Artery in the Upper Third of the Forearm.—Here the artery runs in the space which separates the supinator radii longus from the pronator teres and palmaris longus, covered by the internal border of the first of these muscles, and of course by the fascia and the skin. It is always accompanied by two veins, and has the radial nerve at its outer side. Its course is accurately indicated by a line drawn from the middle of the bend of the elbow to the mid point between the styloid process of the radius and the tendon of the palmaris longus.

In the direction of this line, M. Roux makes an incision about two inches and a half in length, commencing a little below the elbow. If the median vein is met with, it is pushed aside. The fascia is then slit up with a director, and the border of the long supinator drawn outward, without dividing it. The artery having been brought into view, the aneurism-needle or eye-probe is passed under it from without inward, on account of the nerve. (See *Manec, Man. de Méd. Opér.*, p. 164.)

Ligature of the Ulnar Artery at the Wrist.—Here the artery passes on the radial side of the pisiform bone, with the ulnar nerve on its outer side, and a vein on each side of it. In this place

an incision two inches long is to be made through the skin, cellular tissue, and palmar fascia, one after the other. The artery having been thus exposed, an eye-probe is to be passed under it from without inward.

Below the middle of the forearm the ulnar artery is superficial, and may easily be taken up by making an incision upon the radial side of the flexor carpi ulnaris, between the tendon of which muscle and that of the flexor profundus digitorum the vessel is situated. The artery, however, will not be reached until a thin aponeurosis under the fascia of the forearm has been divided. The nerve is rather more under the tendon of the flexor carpi ulnaris than the artery. When the ulnar artery arises from the brachial above the elbow, it pierces and runs above the fascia, and is easily taken up in any part of its course.

For bringing into view the *ulnar artery at the upper third of the forearm*, the situation and breadth of the flexor carpi ulnaris muscle must first be ascertained. An incision is then to be made from above downward, beginning two inches below the inner condyle of the humerus, and following the course of the inner margin of the above muscle to the extent of two inches and a half. The fascia is then to be divided, and the flexor carpi ulnaris drawn a little away from the flexor sublimis. In this opening, rather under the margin of the latter muscle, the ulnar artery will be felt with the finger, continuing its course over the flexor profundus. The ulnar nerve is situated on the ulnar side of the artery. Mr. Guthrie's opinions respecting the propriety of dividing the muscles which conceal the upper third of the ulnar artery have been noticed in the beginning of the present article.

Ligature of the Anterior Tibial Artery on the Foot.—The anterior tibial artery becomes superficial about six inches above the ankle, from which point it descends between the tendon of the tibialis anticus and that of the extensor of the toes. It passes with these tendons under the annular ligament, and rather nearer to the internal malleolus than the external; thence inclining inward, it penetrates between the first and second metatarsal bones to the sole of the foot, where it inosculates with the external plantar artery. The inner branch of the deep dorsal nerve of the foot is at its inner side, its corresponding vein at its outer side. It is covered, 1st, By a thin fibro-cellular expansion, separating it from the adjoining tendons. 2dly, By adipose cellular tissue. 3dly, By the fascia of the instep. 4thly, By the common integuments. On the instep, the first tendon of the extensor communis digitorum pedis lies upon the outer side of the artery; that of the extensor of the great toe upon its inner side.

An incision two inches and a half long is made in the skin, in the direction of an oblique line from the middle of the instep to the first interosseous space. The skin, adipose substance, and fascia are to be divided, the fibro-cellular aponeurosis between the tendons of the first two toes opened, and the artery tied, after being separated by means of a director from the accompanying nerve and veins. (*Velpeau.*)

Ligature of the Anterior Tibial Artery in the Leg.—The two upper thirds of this artery lie close to the interrosseous ligament, but lower down the artery advances towards the outer side of the spine of the tibia; consequently, the higher it is, the more deeply it is situated. The two veins accompanying it inosculate across it by several small branches. The anterior tibial nerve crosses over it obliquely inward and downward, though sometimes it continues on its outer side down to the instep. The artery, veins, and nerve are included in cellular tissue, which does not, however, form a true sheath for them. Above, the artery lies between the tibialis anticus and the extensor communis; in the middle of the leg, between the tibialis anticus and the extensor of the great toe; and still lower down, between the extensor of the great toe and the extensor communis.

In order to lay bare the anterior tibial artery a little above the middle of the leg, the finger is to be passed along the outer side of the spine of the tibia, and the breadth of the tibialis anticus muscle is to be ascertained. Along the outer margin of this muscle, an incision is to be made, through the integuments and fascia, two inches and a half in length. The knife is then to be introduced between the outer margin of the tibialis anticus muscle and the extensor longus of the great toe. In this space, at the depth of about an inch, the anterior tibial artery is situated. (See *Haller's Icon. Anat.*, fasc. v., tab. 4; also *J. P. Manec, De la Lig. des Artères*, pl. 12.)

Ligature of the Anterior Tibial Artery in its Lower Third.—The skin, the subcutaneous fat, the cellular tissue, and the fascia, are to be divided in succession to the extent of about three inches, and in the direction of a line drawn from the mid point between the head of the fibula and spine of the tibia to the instep. Then, with a director or the forefinger, the tendon of the extensor muscle of the great toe is to be separated from that of the tibialis anticus, pushing it outward from the extensor communis if the operation be at the upper part of the lower third of the leg, but inward if the operation be done quite at the inferior extremity of the leg. Nothing then remains to be done but to separate the artery from its accompanying veins and from the anterior tibial nerve, which in this part of the limb is at its inner side, having crossed it from the outer in its descent. (See *Manec*, pl. xii., fig. 1; *Velpeau, Nouv. Elém., &c.*, t. 1.)

Ligature of the Anterior Tibial Artery in its Middle or Two Upper Thirds.—Lisfranc makes an incision extending obliquely from below upward, from the spine of the tibia towards the fibula. Having cut transversely through the fascia, the interspace between the tibialis anticus and the extensors is sought for.

In the ordinary method an incision is made in the track of the artery, as determined by the line above specified, about an inch on the outside of the spine of the tibia. The skin and fascia are divided to the extent of three inches. The muscular interspace, at the bottom of which the artery will be found close to the interosseous ligament, is denoted by a yellowish line. In order to convey the ligature round the artery, Velpeau passes a director under it very obliquely, from below upward, and from the fibula towards the tibia.

Ligature of the Posterior Tibial Artery.—From its origin, a little below the poplitæus muscle, to its division into the external and internal plantar arteries, the posterior tibial artery follows very precisely the direction of a line, with a slight convexity inward, from the middle of the upper part of the calf to a point half an inch behind the internal malleolus. Two veins usually accompany it, sometimes forming by their anastomoses a complete network round it. In the upper part

of the leg the posterior tibial nerve lies to the inner or tibial side of the artery, but soon passes over it to the outer or fibular side. In the two upper thirds of the leg the posterior tibial artery is deep seated, lying in the upper third upon the tibialis posticus, in the middle third upon the flexor digitorum communis, while lower down it is separated from the tibia only by fat and cellular tissue. From the gastrocnemius and solæus it is divided by the deep crural fascia, which muscles lie over its two upper thirds. In the lower third no muscles cover it.

In the arch of the os calcis the posterior tibial artery is in contact with the fibrous sheath of the flexor communis digitorum, about half an inch from the posterior border of the inner malleolus. Here the nerve is behind it, the veins at the inner side. The artery is enveloped in cellular and adipose tissue. The internal ligament of the tarsus, a fibrous layer continuous with the fascia of the leg, after covering the artery, becomes blended with the dense cellular tissue interposed between the vessel and the skin. (See *Velpeau.*) Between the internal malleolus and the lower part of the calf, the posterior tibial artery is somewhat farther from the internal edge of the tibia, and the nerve is rather on its outer side than behind it. The deep-seated fascia, which is here very thin, keeps the artery bound down upon the tibialis posticus, flexor longus communis digitorum, and flexor longus proprius pollicis. External to this fascia is the tissue that fills the sheath of the tendon of Achilles, and then the common fascia of the leg directly under the skin.

In the calf the posterior tibial artery is very deeply seated, almost on the same plane as the posterior surface of the tibia, and much nearer to its external or fibular edge than its internal. It is covered by a strong fascia that lies over the flexor muscles, and then by the tibial portion of the solæus; the internal head of the gastrocnemius; the fascia of the leg; the subcutaneous cellular tissue, in which are found the great saphenal vein and the internal saphenal nerve; and, lastly, the skin. (See *Velpeau.*)

Ligature of the Posterior Tibial Artery.—The leg is to be bent and laid upon its outside.

Behind the malleolus internus.—An incision, slightly curved, with its concavity forward, is to commence an inch above, and to terminate an inch below the posterior edge of the malleolus internus, and to be at least three lines behind it. It will, therefore, be between the malleolus internus and the tendon of Achilles. If the operation is to be performed in the hollow of the os calcis, it is necessary, as M. Velpeau directs, to divide the tissues cautiously, layer by layer, and to introduce a director under the fascia previously to its division, lest the artery, which is sometimes very superficial, be wounded. If the incision were made too near the malleolus, the fibro-synovial sheath of the groove, which that process contributes to form, would be opened; if too far backward, the artery would be more difficult to find. (See *Velpeau, Nouv. Elém. de Méd. Opér.*, t. i.) In fact, behind the lower end of the tibia, the tendons of the tibialis posticus and of the flexor communis digitorum pass in a kind of furrow. Along with these two tendons, but somewhat nearer to the os calcis, the posterior tibial artery descends to the sole of the foot.

The depth of the posterior tibial artery in the two upper thirds of the leg makes it difficult to take it up in these situations. When necessary, however, it may be exposed, and tied above and below the wound in it, by proceeding as follows: An incision four inches in length is made along the inner side of the tibia; the solæus muscle detached from the bone to the same extent, and reflected. The internal saphænal vein is to be avoided. Under the solæus muscle is found the fascia, which separates the muscle of the calf into superficial and deep-seated. When this fascia has been divided, the posterior tibial artery may be seen or felt, deeply situated running on the tibialis posticus and flexor muscle of the toes. (See *Haller, Icon. Anat.*, fasc. v. tab. v.; *Manec, De la Lig. des Artères*, fol., Paris, 1822, pl. 13.)

The method of trying to take up the posterior tibial artery, by making the incision at the inner and posterior edge of the tibia, is disapproved of by Mr. Guthrie on account of its difficulties. "The operator (says he) has cut his four inches, has turned up the edge of the gastrocnemius, and has insinuated his director under the head of the solæus, which he has also sliced away from the bone. The artery is still an inch inward, bound down by a strong fascia," which "must be cut immediately over, or by the side of the artery; it will not do to separate it from the bone, and then to push it over; it cannot be done." Then, supposing the fascia to be divided in the best way, Mr. Guthrie deems the separation of the two veins from the artery, and the passage of the aneurism-needle under the artery from without inward, so as to avoid the nerve, almost impracticable. "If a by-stander should inquire why this most painful, difficult, bloody, tedious, and dangerous operation is done, the answer would be, solely because it was not usual to make a longitudinal incision in the muscles of the calf of the leg; an incision which, if made by accident, would be pronounced to be one attended with little danger, and not likely to lead to any subsequent detriment." (See *Guthrie on Inj. and Dis. of Art.*, p. 259.)

Instead of this method, Mr. Guthrie advocates the following: An incision is to be made, six or seven inches in length, through the integuments and muscles of the calf down to the fascia. If the case is a gunshot wound, the centre of the incision is to be on a line with the shot-holes; or, if they are diagonal to each other, between them. The smoothness of the fascia points it out; and the loose cellular membrane, connecting the divided muscles to it, allows the edges of this long incision to be easily separated and the fascia cut, so as to expose the nerve, artery, and veins. The tourniquet is now to be unscrewed, and the bleeding denotes where the artery is injured. The knife may be applied perpendicularly to the fascia, and the artery laid bare for three or four inches in extent. (P. 261.) Perhaps the length of the incision, as here described, is rather greater than actually necessary. Five inches will afford a great deal of room; but, where the muscles of the calf are very bulky, it will be requisite to make the wound long.

Ligature of the Peronæal Artery.—Here, in following Mr. Guthrie's directions, the incision should also be made through the muscles of the calf towards the fibular side of the leg; and, after the deep fascia under them has been divided, the artery will be found covered by the fleshy fibres of the flexor longus pollicis at any point below three inches and a half from the head of the fibula. These fibres having been divided, the artery will be found close to the inside of the bone. Above the point specified, the artery lies upon

the tibialis posticus, under the deep fascia interposed between it and the muscles of the calf. No nerve accompanies it.

Ligature of the Axillary Artery.—In proportion as this vessel approaches the hollow of the axilla, it gets nearer to the vein, and becomes surrounded by those nervous fasciculi, by means of which one portion of the brachial plexus communicates with another. Hence, to cut down to the artery in this place in the living body, and to tie separately, is acknowledged to be an arduous task. The difficulty is farther increased by the distance of the vessel from the surface. Hence M. Manec objects to any attempt being ever made to apply a ligature to the artery between the pectoralis minor and the lower border of the subscapularis. Independently, says he, of the difficulties of the operation, this part of the axillary artery would be unfavourable to its success, on account of the several branches which are given off from it, near one of which the ligature must be placed.

Directly the axillary artery has arrived opposite the lower border of the great pectoral muscle, the difficulty ceases. Here the brachial plexus no longer exists; each of the different nerves arising from it has taken the course to its particular destination, and the artery is only covered by the integuments and fascia. Behind, it rests upon the tendons of the teres major and latissimus dorsi; in front, it corresponds to the coraco-brachialis, from which it is separated by the median nerve. At its inner side are the internal cutaneous nerve and the axillary vein, which sometimes consists of two or three branches, and renders the dissection of the artery more tedious. Farther backward than the axillary vein are the ulnar and musculo-spiral nerves. The relation of these last nerves to the artery it is of great importance to recollect, in order that neither of them may be mistaken for the median nerve.

In the operation of taking up the extremity of the axillary artery, the patient should be placed upon his back, and the arm raised from the side. An incision two inches and a half in length is to be made six or eight lines behind the anterior margin of the axilla, through the skin and subcutaneous cellular tissue. A piece of the fascia is then to be lifted up with the forceps, and an opening made in it by cutting transversely, close to the end of the forceps; then a director is to be passed into the opening, and the fascia slit up to the extent of the external wound. If the fascia be tough and dense, so as not to afford convenient room, Manec recommends the incision in it to be converted into a crucial one. These things having been accomplished, the farther use of the knife is not necessary. The anterior edge of the wound being now lifted up, the coraco-brachialis will be seen, and the median nerve at its inner side. This nerve being detected, the artery will be found behind it.

M. Manec offers valuable cautions with reference to the manner of avoiding the serious mistake of supposing the ulnar or muscular spiral nerve to be the median. To escape this blunder, he very properly insists upon the prudence of proceeding backward from the coraco-brachialis, for in doing so the first nerve arrived at is the median. (See *Manec, Traité de la Lig. des Artères*, fol., Paris, 1832, Expl. of pl. 6.) In the case of a wound, however, the surgeon has not exactly the choice of the place for the application of the ligature to the axillary artery. Here he must obey the rule of applying it to the wounded part of the artery, and putting one ligature above and another below the bleeding orifice; or, if the artery be completely severed, both its extremities will require to be tied.—C.]

ARTERIOTOMY (from *ἀρτηρία*, an artery, and *τέμνω*, to cut). The operation of opening an artery, and taking blood away from the system in this manner for the purpose of preventing, alleviating, or curing disease. The only arteries of any size from which blood is ever taken in practice are the trunk and branches of the temporal artery, which lie in such a situation that, after the due quantity of blood has been taken away, the bleeding can be readily stopped by compressing the wounded part of the vessel against the neighbouring portion of the cranium. A narrow, sharp pointed bistoury, or a lancet, a basin for the reception of the blood, a compress, and a roller, are the only things required. In general, it is best to open the trunk of the temporal artery; but sometimes its frontal or occipital branch will yield blood enough. But, in many instances, it is better first to make a cut in the skin, and then puncture the vessel. In all cases the surgeon should recollect, 1st. That the temporal artery and its branches are covered by the skin, adipose cellular tissue, and a thin aponeurosis. 2d. That the trunk of the artery divides in the temple, about fifteen lines above the zygoma, and is situated about four lines in front of the meatus auditorius. 3d. That its frontal branch runs forward from its origin, and its occipital branch in the opposite direction. A good place for the puncture is about four lines above the zygoma. In taking away blood from the temporal artery or one of its branches, the surgeon should never forget the fact that the loss of arterial blood produces a more debilitating effect than that of venous; but, in many instances, the requisite quantity of blood cannot be drawn by this operation, as every surgeon of experience must have observed. In order to prevent the blood from trickling down over the bedding or clothes when it does not issue in a jet, the French make a little gutter with a piece of card for conveying it into the basin. After the proper quantity of blood has been taken away, a graduated compress and the nodose bandage are applied. The latter consists of a simple band, four yards long and two fingers' breadth wide, rolled up into two heads of unequal size. The unrolled portion being applied over the graduated compresses that cover the wounded artery, the surgeon conducts the two heads, before and behind, to the opposite temple, where he crosses them in order to return to the point of departure. He now gives them a turn or twist, which enables him to carry one over the summit of the head, and the other underneath the chin to the sound side, where they meet and cross, as in the first instance. Thence they are conducted in the same course to the point of departure, and a second twist being effected, they are conducted for the third time to the opposite temple, and for the third time returned also horizontally and knotted: being conducted finally, one over the vertex and the other underneath the chin, the bandage is terminated by a few circulars of the long head. (See *Cutler's Surgeon's Practical Guide in Dressing, and in the Methodic Application of Bandages*, p. 46, 12mo, Lond., 1834.) A graduated compress, and a few turns of a roller round the forehead, temple, and occiput, are generally preferable to the foregoing bandage, the part of which extending under the

thin is often very irksome to the patient. In a few cases, notwithstanding pressure, the blood bursts forth from time to time; and when this happens, it is best to cut the vessel completely across, which will enable its ends to retract and contract, and thus promote the process of nature in closing them. In three or four days the wound is generally healed, but occasionally an aneurism follows; an interesting memoir on which subject has been published by M. Desruelles. (See *Mém. de la Soc. Méd. d'Emulation*, t. ix., p. 277.) In one instance, Cavallini effected a cure by dividing the vessel and compression. (See *Collez di Casi Chir.*, t. ii., Firenze, 1762.) Sir Benjamin Brodie informed me of a case which he treated successfully in a similar manner. In the course of the present year, 1836, a woman was under my care in the North London Hospital for a temporal aneurism, which followed cupping on the temple. As the blood found its way freely into the tumour after one branch had been tied, I divided another, and applied a compress; the plan was then effectual. Sir Astley Cooper informed me of a temporal aneurism which was produced by a person falling with his temple against the corner of a table.

M. Blandin had a patient who, in consequence of arteriotomy, suffered acute pains, which extended to the top of the head, in the track of the superficial temporal nerve; this consequence, which is uncommon, may be relieved by lengthening the puncture or incision at each of its angles, or even cutting out a portion of the nerve. (See *Dict. de Méd. et de Chir. Pratiques*, t. xiv., p. 422.)—C.]

[ARTERITIS. *Inflammation of an Artery.*—As the coats of arteries possess vessels and nerves of their own, and have an organization more or less similar to that of all the living textures of the body, they must be liable to inflammation, suppuration, ulceration, and gangrene, as well as other morbid changes, especially a deposite of calcareous or atheromatous matter between the inner and middle coats. Arteritis, as contrasted with phlebitis or inflammation of veins, is much less perfectly understood, so far as the symptoms and diagnosis are concerned. It is very certain, however, that the arteries are not so irritable as the veins, and, consequently, that arteritis is less frequent than phlebitis. Pathologists divide it into *acute* and *chronic*. The anatomical characters of the acute are, redness of the internal membrane of the artery affected, an effusion of plastic fibrine on its inner surface, thickening of its substance, and sometimes ulceration. When inflammation runs from a wound, or some other point of irritation, along the internal coat of an artery far towards the heart, it is like phlebitis; a formidable disease, rapidly producing great irritative fever, an extremely quick pulse, complete collapse, low delirium, and generally death. Arteritis, by completely obstructing a main artery and its principal branches, is sometimes a cause of mortification. The treatment of acute arteritis consists in bleeding, purgatives, diaphoretics, low diet, cooling diluent drinks, and perfect tranquillity. Digitalis, tartrate of antimony, and super-acetate of lead, are also prescribed on the principle of calming the circulation; but, as Dr. Hope observes, they must be used with discretion. (See *Cyclop. of Pract. Med.*, part ii., p. 149.) After the first violence of the inflammation has been checked, mercury is sometimes given, so as to excite gentle but quick salivation.

Chronic arteritis is more common than acute. The internal membrane becomes thickened, softened, and of a deep, dirty red colour. "These appearances (says Dr. Hope) are not uniformly diffused, but more marked in the vicinity of calcareous and other degenerations. Hence some have supposed that these degenerations were the cause of the inflammation. There can be little doubt that they tend, in many instances, to keep it up; but it is highly probable that the degenerations themselves were originally caused by increased vascular actions of a chronic nature." (*Cyc. of Pract. Med.*, pt. ii., p. 145.) The formation of spontaneous aneurisms is now commonly believed to have its origin in chronic arteritis.—C.]

[ASPHYXIA (from *a*, privative of, and *σφύξη*, the pulse). Cessation of the action of the heart from the interruption of respiration, or, rather, of the effect produced by that function on the blood.

Asphyxia may also be defined to be a suspension of the phenomena of respiration, occurring primarily, and followed by that of all the other functions, and frequently by death. The general causes of asphyxia may be arranged under three principal heads. 1. Asphyxia from deficiency of air. 2. From the air being unfit for respiration, yet not producing any deleterious effect on the economy. 3. From the inspiration of some gas which is deleterious. As M. Duvergie rightly observes, however, the suspension of functions, or the mode of death in the last case, is very different from what is exemplified in the first two; because it is, in fact, a kind of poisoning brought about by the action of a deleterious principle either on the nervous system or the blood, and the individual may perish though he is actually respiring air. (See *Duvergie* in *Dict. de Méd. et de Chir. Prat.*, art. Asphyxie.)

Cases of asphyxia admit of a classification, first, into those in which there is primarily a stoppage of the mechanical phenomena of respiration, and, secondly, into others in which the chemical phenomena are primarily interrupted. As examples of the first mode of asphyxia, it will suffice to mention those in which the muscles of inspiration cannot act. 1. This happens where a heavy mass of earth or other materials suddenly falls upon a man, and makes great pressure on the chest or abdomen. 2. Where the nervous influence does not extend to these muscles, as where the medulla spinalis is injured high up, or the phrenic nerves have been paralyzed by the effect of lightning. 3. Where the same muscles are in a state of inaction from the influence of intense cold. Asphyxia, from the passive expansion of the lungs not taking place, may be exemplified in cases where the abdominal viscera are forced through an accidental or natural opening of the diaphragm into the chest, or when the lungs are compressed by fluid in the cavity of the pleura, and various other causes.

Asphyxia depending upon the primary cessation of the chemical phenomena of respiration is of two kinds. In one, it arises from some mechanical impediment to the entrance of air into the lungs, as in cases of foreign bodies entering the trachea, submersion, hanging, &c.; in the other, it depends upon a deficiency of air fit for the purposes of respiration.

Asphyxia may be the original affection, or it may be only the termination of another disorder. Thus a person is attacked by pneumonia, and dies of asphyxia, caused by hepatization of the lungs; or he is seized with pleurisy, and is ultimately destroyed by an effusion of serous fluid in

the chest. (See *M. Duvergie* in *Dict. de Méd. et de Chir. Prat.*, art. Asphyxie.)

As the salutary effect of respiration depends upon the air which is respired containing a due proportion of free oxygen, the deficiency or absence of this element must necessarily produce asphyxia. On this principle, azote, hydrogen, carbonic acid gas, and air too highly rarefied, will cause asphyxia. Carbonic and some other gases act fatally also, on the principle of being positively deleterious to life when introduced into the air-cells. One manner in which asphyxia may be occasioned is by submersion, the lungs of warm-blooded animals not having an organization qualifying them to derive from the oxygen contained in water the salutary influence on the blood which they collect from the respiration of atmospheric air.

Asphyxia may likewise arise from various circumstances preventing the entrance of air into the lungs, as the lodgment of a foreign body in the larynx, trachea, or œsophagus; a swelling of the membrane of the larynx; obstruction of this organ and the trachea with fibrine, as in croup; tumours formed near, or pressing upon some part of the respiratory tube, and pressure upon the same organ from any other cause, as is exemplified in strangulation. It has been explained that some causes of asphyxia operate by destroying the mechanism of respiration, that is, by rendering the muscles concerned in this function paralytic. Thus an injury of the medulla spinalis, as high up as the third cervical vertebra, by destroying the influence of the phrenic nerves, will paralyze the diaphragm. It will, at the same time, paralyze the other principal muscles concerned in producing the requisite changes in the dimensions of the chest; and, consequently, a fatal asphyxia must take place. This was well illustrated in a case lately brought into the North London Hospital. The ends of the neck-handkerchief of a youth, aged fifteen, were caught by the wheel of some machinery, which drew his neck with great force against the works, and, at the same time, caused violent strangulation. In about one minute the handkerchief was cut through and the constriction removed: he was brought to the hospital with his respiration stopped, and asphyxia from this cause. Attempts were made to restore respiration and the action of the heart, first, by blowing air into the lungs through the nostrils. Whenever this was done, the action of the heart returned, the pulse rose, and the livor of the lips and countenance disappeared; but as soon as the inflation of the lungs was discontinued, then the pulse sunk so as to become undistinguishable, and the skin assumed the purple colour again. Finding that this happened repeatedly, a suspicion was entertained that the cervical vertebræ had sustained injury; but, in order that the inflation of the lungs might have every chance of doing good, in the event of other injury not existing, I performed tracheotomy, and air was introduced into the lungs with a pair of bellows and a tube. All this, however, was in vain; and galvanism was equally unsuccessful. The boy was kept in a state exhibiting signs of life for about six hours from the period of the accident; but his temperature continuing to get lower and lower, he at length sunk. In the *post mortem* examination, a fracture of the arch of the third cervical vertebra, a laceration of the front ligament of the spine, an effusion of blood on the medulla, and also another effusion behind the pharynx, were detected.

Formerly, the cessation of the action of the heart in hanging or drowning was referred to a mechanical impediment to the transmission of blood through the lungs to the left cavities of the heart. But the experiments of Goodwyn and others prove that no such mechanical obstruction exists, and that, even after the fullest expiration, the air remaining in the air-vesicles of the lungs distends them sufficiently to permit the blood to circulate freely through them. The real obstacle arises out of the interruption of those chemical changes which atmospheric air produces on the blood while circulating in the pulmonary vessels, and which convert it from venous to arterial blood. In fact, the blood, which in asphyxia thus retains its venous character, does for a time pass through the pulmonary circulation, and is conveyed into the left ventricle, which propels it into the aortic system of arteries. But this blood, which is thus substituted for arterial, has deleterious properties, depriving the organs to which it is sent of the power of performing their respective functions. Sensibility, irritability, together with all the physical and vital actions depending upon them, are suspended. (See *Roget* in *Cyclop. of Pract. Med.*, art. Asphyxia.) From the investigations of Bichat, it appears that the primary effect of the circulation of venous, or what he calls black blood, is on the brain, and that this effect extends, through the intervention of the brain, to the whole nervous system. Loss of sensibility therefore precedes the suspension of the action of the heart, and takes place as soon as the venous blood sent into the arteries reaches the brain. (See *Bichat, Recherches sur la Vie et la Mort.*)

The face of a person who has been drowned is in general pale, though slightly livid. A frothy liquid, and some water, are found in the trachea, bronchi, and air-cells of the lungs: the latter organs are of a violet colour, but contain less blood than where asphyxia has been occasioned by carbonic acid gas; the right auricle and ventricle are filled with black blood; in the stomach there is generally more or less water, which has been swallowed; the surface of the brain is of a darker appearance than usual, but its vessels not particularly turgid; and the air remaining in the lungs contains little oxygen. (See *J. F. Berger, Essai sur la Cause de l'Asphyxie par Submersion*, Genève, 1805; *Goodwin on Connexion of Life with Respiration*, p. 19.)

When the person, at the time of falling into the water, was intoxicated, stunned by a blow on the head, or in a state of syncope, there can have been no struggle. Under such circumstances, the trachea will contain a little water, but no froth; the lungs will be of their natural colour, and not much expanded; no water will be found in the stomach; and the blood in the venous system will not be so disproportionate to that contained in the arterial. As Dr. Roget justly observes, the great diversity in these and other circumstances "will enable us, perhaps, to explain the differences that are met with in the time during which the body may remain under water compatibly with the possibility of restoring life. If the submersion have not exceeded five minutes, and no blow against a stone or other violence has occurred to complicate the effects, our efforts at resuscitation, if properly conducted, will generally be successful. After a quarter of an hour, recovery is not very common; after twenty minutes or half an hour, it may be considered as nearly hopeless. The longest pe-

riod recorded in the Reports of the Humane Society is three quarters of an hour. On the other hand, some, who have been only a few minutes under water, cannot be restored to life, even by the prompt application of proper means." (*Dr. Roget*, in *Cycloped. of Pract. Med.*, article Asphyxia.)

In the endeavour to resuscitate a person whose animation has been suspended by immersion, the wet clothes should be promptly removed, and the body covered with blankets and placed on a table, with the head and chest raised; the nostrils and mouth are to be freed from froth, and kept perfectly unobstructed. The lungs are then to be inflated with the kind of bellows employed by the Humane Society, and provided with a short flexible tube, one end of which is adapted to the nozzle of the bellows, and the other to a silver tube, designed for introduction into the nostril. As the glottis is open, air, conveyed into one of the nostrils, while the other and the mouth are closed, and the larynx is pressed towards the vertebræ so as to close the œsophagus, must necessarily pass into the lungs. The lungs being thus filled, are next to be emptied, by an assistant compressing the chest and expelling the air. The same operations are to be repeated until natural respiration begins, or until this and other approved measures have been tried at least six hours. (*Dr. Curry, Obs. on Apparent Death, &c.*) When this method fails to fill the lungs with air, tracheotomy may be performed, but in the opposite case it is not necessary. As the body is insensible, there is, indeed, commonly little or no difficulty in passing any bent tube of moderate diameter and proper length into the glottis when the tongue is drawn forward, and tracheotomy, under these circumstances, cannot be needed. Thus, with an ordinary silver catheter, air may be blown into the lungs. Together with inflation of the lungs, gentle friction of the body with warm flannels or the hand, stimulating the nostrils with hartshorn, and injecting warm stimulating fluids into the stomach with a syringe and tube passed down the œsophagus, are plans generally recommended. Slight shocks of electricity or galvanism through the heart and diaphragm may also be tried, if the apparatus be ready at hand.

After the breathing has been restored, the patient is to be watched, lest he yet fall a sudden victim to a returning accumulation of black blood in the brain, or to the violent effects of reaction in the system.

The treatment of persons whose animation is suspended by *strangulation* is the same as that of persons in a similar condition from submersion. Here, however, the fulness of the sinuses of the brain may render bleeding indispensable.

In cases of asphyxia depending upon obstruction of the glottis, larynx, or trachea by disease, foreign bodies, or tumours, tracheotomy or laryngotomy, according to circumstances, is frequently the only means by which life can possibly be saved. (See LARYNGOTOMY and TRACHEOTOMY.)

The treatment of asphyxia from carbonic acid gas consists in removing the body immediately into the fresh pure air, sprinkling it with cold water if its temperature be high, galvanizing it, and endeavouring to restore the breathing by blowing air down the glottis: oxygen gas, if at hand. Differences of opinion are entertained about the utility of bleeding.—C.]

[ATROPHY (from *a*, privative, and τροφὴ), nutrition). A deficiency in the nutritive powers of a part, in consequence of which its natural dimensions are reduced, and the number of its constituent molecules diminished. (*Townsend*, in *Cyclop. of Prac. Med.*, art. Atrophy.) According to another pathologist, atrophy is degeneration of growth, deficiency in the size and weight of a part, and commonly of one or more of its usual constituents in particular. (*Mayo, Outlines of Human Pathology*, p. 16.) When the functions of organs cease or are long suspended, an atrophy of them usually follows. Thus, in a limb kept for a long while unexercised in consequence of disease, the bones suffer atrophy as well as the soft parts. But certain states of disease and injury frequently lead to atrophy of various organs and textures. This fact is often exemplified in the testicle. Wounds of the occiput and back of the neck were remarked by Larrey in Egypt to be often followed by atrophy of this organ. The want of a free supply of blood and nervous energy leads necessarily to weakness and atrophy of parts. In old age, various parts undergo what is termed *senile atrophy*. Thus, in advanced life, the ovaries and mammary glands are reduced to mere rudiments.

According to Dr. Carswell, atrophy "is the modification of bulk which takes place in consequence of a diminution in the quantity of the solid materials which enter into the healthy composition of organs and tissues." This diminution of bulk, which constitutes the essential physical character of atrophy, is described by him as depending upon diminished exercise of the nutritive functions. (See *Carswell's Illustrations of the Elementary Forms of Disease*, p. 10.) In this valuable work, one of the most correct ever published on this interesting branch of pathology, notice is taken of certain forms of *congenital atrophy*, as exemplified in *monstrosities*, and occurring as the consequences of the formative process having been arrested at certain periods of the evolution of particular organs. Dr. Carswell next adverts to the atrophy, or even total disappearance of organs soon after birth, which performed functions essential to the existence of the fœtus, but which are now no longer necessary to the maintenance of life, as the ductus arteriosus, umbilical arteries, the thymus gland, supra-renal capsules, &c. Different from these two forms of atrophy is that which, as Dr. Carswell observes, takes place in advanced life, "as the fulfilment of a general law of nature, so conspicuously manifested in the limited duration of all organized beings, which, having attained the maximum of their development, decline after a variable period of time, and tend gradually towards decay." *Senile atrophy*, as Dr. Carswell terms it, is carried to a great extent in the vesicular structure of the lungs, the spongy structure of the penis, the testes, the lymphatic and mammary glands, the uterus, and ovaries. The bones, in general, lose much of their weight; and, as every surgeon of experience knows, fracture of the neck of the thigh-bone is rendered common in old persons, in consequence of the effects of senile atrophy. After seventy, the brain is diminished from $\frac{1}{15}$ to $\frac{1}{20}$ of its average weight, and becomes specifically lighter, and the trunks and branches of the nerves are reduced in size. The muscles, especially those of voluntary motion, participate likewise in the general decay, and so do the bloodvessels, which always bear a relation to the increased or reduced size of th organs to which they are distributed.

This fact is exemplified in the size of the large, or the number of small arteries being lessened. The general interstitial absorption of John Hunter, the atrophy of the whole body, or the marasmus and emaciation from diseases deranging the important functions of digestion, respiration, and the qualities of the blood from fevers, profuse suppuration, and various severe and organic diseases, I need not consider in this place. But, besides these forms of atrophy affecting the whole body, there are others which are local, and divided by Professor Carswell into three classes. 1. Atrophy from a diminished supply of blood. 2. From diminished exercise of the function of innervation. 3. From diminished exercise of the functions of the organ. For numerous original, philosophical, and practical remarks on these heads, I refer to *Carswell's Illustrations of the Elementary Forms of Disease*, fasc. 10.—C.]

B.

[BANDAGES. The surgical world are indebted to Professor Dudley, of Kentucky, for the just estimation and extensive adaptation of the bandage as a therapeutic agent. Its early application after recent injuries and operations will be found of great importance in controlling the circulation and facilitating the cure.

During the year 1835, Dr. H. Chase, of Philadelphia, introduced to the profession a novelty in the construction of suspensory bandages. He substitutes non-elastic (linen) bandages for those commonly made of silk, cotton, or other elastic materials. They vary in shape from those in ordinary use, the sac in each instance being adapted to the size of the scrotum, and the band supporting the sac passing upward over each groin, and around the body above the anterior superior spinous process of the ilium.

The principle of action consists in the constancy and unavoidability of the support and pressure, by which the undue contents of the enlarged spermatic veins are expelled from these vessels. He has seldom found these bandages to fail in relieving patients from all the painful symptoms attendant upon cirsocele, and, in an equal number of cases, to eradicate all traces of this complaint.

A full description of this instrument, together with its mode of action, is given, accompanied with cases, in the Appendix to the "*Final Report of the Committee of the Philadelphia Medical Society on the Radical Cure of Hernia by Trusses. Republished, with Notes, by Heber Chase, M.D.*, p. 217.—REESE.]

[BLADDER. The operation of cutting into the membraneous portion of the urethra, behind the stricture, seems to me one of the greatest improvements in modern surgery; for, as it is chiefly in a few cases of stricture that an artificial outlet for the urine is required, the new plan, which, as compared with a wound of the bladder, is a trifling injury, nearly obviates all necessity for puncturing the bladder in any way.

This plan was first adopted and recommended by Sir Astley Cooper, and it afterward had an advocate in Sir Charles Bell.

I lately placed in the Museum of University College a scirrhous tumour, which I found in the bladder of an elderly man, whose thigh-bone broke as he turned himself in bed, in consequence of being weakened by the pressure of a cancerous tumour upon it. (See *Med. Chir. Trans.*, vol. xvii., p. 51.)

BLADDER, HERNIA OF. See HERNIA.

Besides this case, the bladder in females is liable to prolapsus and inversion, through the meatus urinarius.

BLADDER, HYDATIDS VOIDED FROM.

This case is exceedingly rare. In one example, under Dr. Duncan, the hydatids discharged from the urethra were formed in the kidney. The symptoms were frequent desire to make water, and sometimes difficulty in making the evacuation, and pain about the hip, perineum, and glans penis. The pain in the perineum was generally felt six or seven hours before each hydatid was expelled. The expulsion of the hydatids was promoted by exhibiting twelve minims of diluted muriatic acid thrice a day. The hydatids voided were of a globular shape, and of the genus acephalo-cyst, and varied in size from that of a pea to that of a pigeon's egg. Probably they had enlarged after their descent into the bladder. (See *Liverpool Med. Journ.* for July, 1834.)

The following curious account of the post mortem appearances in an instance of this kind is given by Dr. Tyson: "Therein, upon operation (says Dr. Tyson), we discovered a very strange sort of cystes, or bags, of the exact figure of eggs, of several dimensions, some larger than goose eggs, others as big as hen eggs, to the number of twelve in all; and about eight of them whole, and replete with limpid serum: all of them loose and free, without the least adhesion, either to one another, or the coat of the bladder. Nor could we imagine that this miserable patient could possibly make any water but what happened upon the breach of some of these watery tumours, when the bladder was crowded beyond its dimensions. The ureters were of the largeness of the small guts in children, so that they could easily admit two fingers into their cavity One of the vesiculæ being opened, had a large cluster of small ova, as big as grapes, all replete with liquor. All the rest contained nothing but serum." (*Tyson in Philos. Trans.*, 1687.)

BLADDER, INSECTS DISCHARGED FROM.

About two years ago I received from Mr. Law, of Penrith, Cumberland, many specimens of substances voided from a young woman's bladder, supposed by him to be portions of tæniæ. But, on submitting them to the examination of Mr. Richard Owen, at the College of Surgeons, he ascertained, perfectly to his own satisfaction, that the substances were only pieces of the intestines of pigeons, or other small birds, cut and prepared so as to bear some resemblance to taniæ; and, consequently, that the woman is guilty of some trick or imposture, from monomania or other inexplicable cause. Mr. Law seems convinced, however, that the case is different from the view of it taken by Mr. Owen.

BLADDER, RUPTURE OF THE.

Many examples of this accident, occasioned by blows, or sudden violent pressure on the hypogastric region, and followed by fatal extravasation of urine, are upon record. So fatal is the occurrence, that Dr. Harrison is not aware of any instance, the particulars of which are published, having had a favourable termination. (See *Dublin Journ. of Med. Science*, vol. ix., p. 350.) The urinary bladder, in its empty and contracted state, as he correctly observes, lies so deeply in the male pelvis as to be almost perfectly secured against any injury or accident except that of a gun-shot wound or a surgical operation. When, however, it becomes distended with urine, it rises up above the pubes, presses forward against the abdominal parietes, and is in a position much exposed to external injury. In this state, also, its coats are tense, expanded, and thin; conditions in which their tissue is more easily ruptured. Excluding from present consideration penetrating wounds and lacerations by spiculæ of fractures of the os pubes, the bladder is generally burst by violence, applied directly to the hypogastric region, as by a blow or fall on this part, or the heavy pressure of a cart or carriage wheel. In the museum of University College are two specimens of ruptured bladder; in one the accident was occasioned in the following manner: a man who had been drinking, and whose bladder was very full, went out of the house where his party was, but it being dark, he struck the hypogastric region against a post which he did not see. The consequence was the rupture of the bladder. The other specimen was taken from a fine young man, a patient of my own; the injury having occurred while the bladder was very full of urine, as he was wrestling with another person, whose knee, in the fall, made violent pressure on the abdomen, just above the pubes. Also, the accident has sometimes been caused by a general concussion of the whole frame, such as a fall from a height, without any direct force acting on the cesical region itself. (See *Cusack's case in Dublin Hospital Reports*, vol. ii.) Again, the bladder may be ruptured by violent exertion, and repeated straining to empty it when over-distended, in consequence of some obstruction to the flow of urine, or during the violent efforts of parturition. Lastly, it sometimes gives way from gangrene, when it has long been in a state of forced distension, or when, being in a state of plenitude, it is subjected to the long-continued pressure of the uterus during a protracted labour, or, in the earlier periods of utero-gestation, to the pressure on it caused by a retroversion of the womb, as exemplified in the cases recorded by Dr. William Hunter. (*Med. Obs. and Inq.*, vol. iv. and v., Lond., 1771; *Harrison in Dublin Journ. of Med. Science*, vol. ix., p. 352.) In retention of urine, a rupture of the bladder from straining to empty it, is not a common event. One instance of it is mentioned by Sir Benjamin Brodie (*On Dis. of Urinary Organs*, p. 12), and another by Sir Everard Home. (*On Strictures*, vol. ii., p. 240.) But, as Dr. Harrison observes, it is doubtful whether, in the latter case, the opening in the bladder was the effect of a sudden laceration, caused by muscular exertion, or of some preceding ulcerative or gangrenous affection at the particular point where the organ gave way. Generally, however, in retention of urine from stricture, when the urine becomes effused, it is not from a rupture of the bladder, but from that of the urethra behind the stricture, or in the immediate vicinity of the prostate gland. (*Harrison in Dub. Journ. of Med. Science*, vol. ix., p. 352.)

It would appear from Dr. Harrison's investigations, that, when the distended bladder in the male has been ruptured by a fall or blow on the hypogastric region, or by a general concussion, that portion of it which is covered by the peritoneum has very generally been the seat of rupture; the urine has consequently been effused in the abdomen, and the patient has been destroyed by peritonitis (p. 354).

The following is the explanation offered by Dr. Harrison of the fact that, when the bladder is ruptured by a blow or general concussion, the laceration is always found in that part of the organ which is covered by the serous membrane. "The several tunics of the bladder allow of considerable distention, but least of all the peritoneal: when, therefore, the bladder becomes fully distended, and is then subjected to any sudden or violent compressing force, this tunic, which is then tense, and comparatively unyielding, will crack, while the subjacent tunics which are connected to it will be torn along with it; whereas, in other situations, where cellular tissue occupies the place of the serous membrane, the coats of the bladder will yield considerably before they give way or admit of laceration. (See *Dublin Journ. of Med. Science*, vol. ix., p. 371.) The bladder being pressed forcibly against the promontory of the sacrum in the male, seems to Dr. Harrison also to account for the rent being usually in the posterior region of that viscus. The rarity of the accident in females is ascribed by him to the greater size of the pelvis, the cavity of which is not so extensively occupied by the bladder when this is full of urine. Nor (says he) does the bladder incline so much backward as in the male; on the contrary, it inclines more forward, and enlarges more in the transverse direction, while the uterus and its lateral broad folds may assist to break the shock of any external violence applied to the hypogastric region, and so prevent the direct concussion of the bladder against the sacral promontory." (Vol. cit., p. 372.) The comparative unfrequency of a rupture of the bladder in children and boys is referred by Dr. Harrison to their rarely suffering the bladder to become much distended with urine, and in part to the smaller size of the sacral promontory, and to the bladder, when full, lying in early life more in the abdomen.

With respect to the diagnosis of the kind of rupture of the bladder now under consideration, it is judiciously observed by Dr. Harrison that, as it is the effect of only two species of injury, the account of the accident will afford useful information. Thus, says he, every case on record has been the result either of some force directly applied to the abdomen, or of a general concussion of the whole frame. In this latter case the injury is more likely to be overlooked, particularly if the individual has suffered in any other and more obvious manner: hence, after such accidents, the attention of the practitioner should be early directed to the urinary discharge, and, if there be any inability to pass the urine, and a desire to do so, the catheter should be introduced. When the rupture has been the effect of violence directly applied to the hypogastric region, the symptoms are more obvious. The patient himself is often aware of the accident: he knew that his bladder was full at the time of

the injury; perhaps he felt it burst within him. Then the sensation of sinking and sickness, the pain in the abdomen, and the peculiar feeling about the præcordia, are all circumstances indicative of the rupture of some viscus. In addition to these symptoms, there will be a desire to make water without the power of doing so; great pain in the belly and perineum during the attempts; tension of the abdomen, the fulness being diffused, and not circumscribed, as in common retention of urine. When a catheter is introduced into the bladder, it meets with a peculiar resistance, and the urine flows through it, not in a stream, but as if it merely filled and overflowed the instrument slowly; at one time only in a few drops, at another in considerable quantity; "this difference depending on some alteration in the direction of the instrument, or in the degree of pressure with which it is pushed against the bladder, whereby the edges of the rupture must be separated, and more or less of the abdominal and pelvic urine be discharged." (See *Harrison* in *Dub. Journ. of Med. Science*, vol. ix., p. 377.)

In one case, recorded by Mr. Cusack, only a few drops of urine could be drawn off with the catheter on the day of the accident. On the next no urine flowed at first; but, by changing the direction of the instrument, and on making pressure with the finger in ano, about three pints were discharged. On the third day, as all the symptoms continued unabated, the abdomen was punctured in the linea alba, midway between the umbilicus and the pubes; and a large quantity of clear urine escaped, and, at the same time, it flowed freely from a catheter in the urethra. The relief was only temporary, the patient having died delirious on the eighth day. On dissection, marks of intense inflammation were noticed in the hypogastric region, where the intestines were glued together into one mass. At first no urine was seen; but, on breaking the adhesions and raising up the intestines, about a pint of it was sponged out from between the rectum and the bladder. "The pelvic portion of the peritoneum was completely coated with lymph; the bladder was contracted and empty; the rupture, about an inch in extent, was in its posterior part and right side, and in an oblique direction. (See *Cusack* in *Dub. Hospital Reports*, vol. ii., p. 312.)

In the *post mortem* examination of a case under Dupuytren, traces of severe inflammation were observed in the hypogastric region. Adhesion existed between the abdominal parietes and the bladder, and the sides of the latter and the adjacent viscera were all so agglutinated together, that a kind of pouch was formed, considerably advanced in organization, whereby the urine was circumscribed, and effusion to any farther distance prevented. (See *Archives Gén.*, June, 1834, p. 294.) In general, the bladder, though the seat of injury, is itself but little inflamed, except at the posterior portion of its serous coat. (See *Harrison* in *Dub. Journ. of Med. Science*, vol. ix., p. 375.)

In the treatment, the principal indications are to withdraw, if possible, the effused fluid from the abdomen; to prevent, if possible, any return or increase of such effusion; and to resist and subdue that unavoidable and very fatal affection peritonitis. With this view, any accumulation of urine in the bladder should be prevented by the introduction of an elastic gum catheter of full size, with a long and large curve; and if, by changing its direction or other manœuvres, its beak can be passed through the rent, or made to reach its vicinity so as to open it, a considerable quantity of urine may be drawn from the cavity of the peritoneum. Pressure with the finger in ano is also to be tried. (See *Harrison*, vol. cit., p. 379.) In the case which I attended, a catheter of full size was kept continually introduced. In this way we endeavour to lessen the exciting cause of the inflammation, which, however, is sure to follow the effusion of so irritating a fluid as the urine. Inflammation must, therefore, be resisted by local and general bleeding; calomel, opium, and mild saline purgatives given with the effervescing mixture. If the disease advance, and the pains in the abdomen become more intense, with swelling and fluctuation, ought the surgeon to perform paracentesis? As Dr. Harrison remarks, this has been done in two instances, but without success. "The urine which is effused is principally lodged in the pelvic cul-de-sac, and is more or less confined to that region, partly from its depending position, and partly from the adhesions which, we have reason to expect, under proper and active treatment, may have been formed between the bladder and the adjacent viscera at the upper orifice of the pelvis." This view leads Dr. Harrison to consider cutting a small opening through the rectum into this cul-de-sac the best and safest plan for the discharge of the irritating fluid. Here a new cavity has been formed, coated internally like an abscess; and the opening is not to be regarded as extending into the general cavity of the peritoneum. The operation might be done with a trocar, or a long curved bistoury, with a sheath, and a cutting edge only on its extremity. The patient being in the recumbent posture, with his knees drawn up and somewhat separated, the finger of the left hand might be passed up the rectum as far as possible, and pressed against its fore part. The catheter in the bladder might also assist in guiding the finger to the cul-de-sac behind that organ. The cannula of a long curved trocar might next be passed along the finger, and, when its extremity had been placed against the fore part of the rectum, exactly in the median line, the stillette might be pushed through it, and the peritoneum opened. Dr. Harrison conceives that the quantity of effused fluid would protect the small intestines from reach of the instrument; and he says that in the cases which he has examined, he did not find any of their convolutions in the pelvis. Supposing this operation were ever attempted, ought the cannula to be left in the part? or ought it to be withdrawn, and the catheter trusted to for the prompt discharge of the urine afterward? The latter method is preferred by Dr. Harrison. (See *Boyer, Mal. Chir.*, t. ix., p. 61; *C. Montague* in *Med. Communications*, vol. ii., p. 284; *Cusack* in *Dub. Hospital Reports*, vol. ii., p. 312; *Dupuytren, Archives Gén.*, June, 1834, p. 294; *Johnstone* in *Mem. of Med. Soc. of Lond.*, vol. iii., p. 543; and particularly *Dr. Harrison's Cases and Obs.* in *Dub. Journ. of Med. Science*, vol. ix., p. 349, to whom I am indebted for the chief information in the foregoing article.)—C.]

[BLEPHAROPLASTIC. Doctor Alfred C. Post, of New-York, has cured two aggravated cases of ectropium of the lower lid, occasioned by the contraction of cicatrices, resulting from burns, by means of the blepharoplastic operation. An incision was first made by which the lid was detached from the cheek throughout nearly its whole extent. A triangular portion of

the everted lid was then excised, and the edges of the wound in the lid brought together with a suture. A vertical flap was then formed from the integument, covering the masseter muscle, and twisted upon itself so as to be inserted between the lid and the cheek, where it was retained by sutures. The edges of the wound from which the flap was taken were also brought together in a similar manner. The deformity resulting from the cicatrices after the healing of the wounds was very trifling, compared with that which had been removed by the cure of the ectropium.

An account of the first of these cases was published, with engravings, in the New-York Medical Gazette for January 19th, 1842.

During the last year, Dr. J. M. Warren, of Boston, has performed this operation for restoring the lower eyelids, which had been partially destroyed by burns, in two cases with entire success.

Dr. Geo. M'Clellan, of Philadelphia, has repeated this operation fifteen times, and with the most gratifying results in removing frightful deformities.

Dr. Mutter, of Philadelphia, has also operated in several cases with gratifying success, and Dr. Horner, of Philadelphia, reports a successful case in the American Journal for 1837.—REESE.]

[BLISTERS. In the North London Hospital, the nitrate of silver is often used for making blisters, as particularly recommended by Mr. Higginbottom. It causes less irritation, and its effects are more prompt than those of cantharides. It may also be used in persons in whom cantharides produce strangury. It excites a copious discharge, without heat or pain after the first few hours, and the vesicated part heals about the fifth day, no ulceration having been occasioned. (See *Higginbottom on Nitrate of Silver*, p. 161.) By means of the application of nitrated silver, repeated every six or eight days, and of perfect quietude of the part, secured by means of a splint and bandage, many a diseased joint has been cured in the North London Hospital.

"In applying blisters to infants," says Dr. Cumming, "we must take particular care not to allow them to remain on for more than three or four hours. When a blister is applied for a longer period, excessive general irritation is apt to be induced; and such is the delicacy of the infant's skin, that the blistered parts not unfrequently become gangrenous. Under such circumstances, the death of the child has been sometimes the consequence. Though vesications may not have formed at the time when the blister is removed, they generally take place after the application of the dressing. In some habits the blistered surface takes on an unhealthy action, and runs into eating and irritable ulcers, which are long in healing. In such cases I have found an emollient poultice, when the inflammation is considerable, and afterward the black and yellow washes, the most useful applications. In infants of an irritable habit, it will sometimes be advisable to dilute the blistering plaster with an equal quantity of the emplastrum ceræ." (*Dr. Cumming in Trans. of Assoc. of Coll. of Physicians, Ireland*, vol. v., p. 55.) See *Paris's Pharmacologia*, vol. ii., p. 186, ed. 5. *A. T. Thomson's Dispensatory, and Elements of Mat. Med.*, ed. 2. *John Higginbottom on the use of Nitrate of Silver*, p. 161, ed. 2, 8vo, 1829. *Mayo's Outlines of Human Pathology*, ch. i.—C.]

[BONES, EXCISION OF. This operation is sometimes applicable to the articular portions of bones, but still more frequently to other parts of them. The circumstances under which it is practised for the removal of diseased or very severely injured joints, and the plans then to be adopted, will be hereafter considered. (See JOINTS, EXCISION OF.) Neither shall I dwell at present upon the removal of the projecting ends of broken or dislocated bones, nor upon sawing off the extremities of old ununited fractures; subjects noticed in the account of *Dislocation* and *Fracture*. In the articles Amputation and Gunshot Wounds, I have called the reader's attention to the praiseworthy method of cutting down to, and removing all loose splinters of the os brachii, and even the sharp end of that bone itself, from certain gunshot injuries of the shoulder, so as frequently to obviate the necessity for amputating the limb. The cases demanding the removal of portions of the scull, and the manner of accomplishing it, will be described under the head Trephine. Towards the conclusion of the observations upon Amputation, some account has already been given of the *excision of certain bones of the hand and foot*. It is difficult, as M. Malgaigne observes, to lay down any precise directions for the *excision of the bones of the tarsus*. The following plan was adopted by Moreau, the father, for an extensive caries: Over the cuboid bone there was one ulcer an inch in diameter, and another between the third and fourth metatarsal bones, resulting from an incision made a few days previously for the discharge of an abscess. A probe penetrated into the cuboid bone. An incision was made along the outer side of the foot, and extended across the ulcer, from the posterior third of the fifth metacarpal bone to above the anterior tuberosity of the os calcis; and, as the incision already made for the abscess could now be made serviceable, this and the other incision were conjoined by a transverse one, and the square flaps reflected. The diseased bones were thus brought into view, and it was necessary to remove the cuboid, the third cuneiform, the posterior end of the fourth metatarsal bone, the inner side of the extremity of the fifth, and the articular surface, by which the os calcis is united with the cuboid bone. The tendon of the peronæus longus was preserved. The flaps were then laid down, and united with two sutures. The patient, who was young, got completely well. The vacancies occasioned by the extrication of the bones were filled up by a substance which afterward ossified. In the end, the patient was able to walk well, the foot having assumed its natural shape and motions. (See *Malgaigne, Man. de Méd. Opér.*, p. 243.) The operation of removing the metacarpal bone of the thumb, or the metatarsal bone of the great toe, is not deemed by Mr. Liston an advisable proceeding, because the rest of the thumb or toe is left without support, and is useless. He has seen cases treated in this way, but the result was unsatisfactory. However, Monro removed the *whole of the first metatarsal bone* on account of caries, and M. Barbier did the same thing at the Val de Grâce after a dislocation of the bone, and in each case the result was in every respect successful. (See *Malgaigne, Op.* cit., p. 243.) The *extraction of the metacarpal bone of the thumb* has been performed with success by M. Roux and M. Blandin. The thumb was at first shortened and useless, but gradually became capable of executing all its natural movements. (See *Malgaigne, Man. de Méd. Opér.*, p. 232.) An incision is to be made along the radial edge of

the bone, and to extend about half an inch beyond each of its articulations. Then the integuments and extensor tendon are to be detached from its dorsal, and afterward the muscles from its palmar surface. While an assistant holds aside the lips of the wound, the surgeon opens the outer side of the carpal joint with the point of the knife, cuts through the tendon of the long abductor, which is inserted into the metacarpal bone, and then carries the knife completely through the joint. He now tries to dislocate the bone outward, and to pass the knife along its inner side, so as to effect its total detachment from the muscles. Lastly, the articulation with the first phalanx is opened by cutting in succession the internal and external lateral, and the anterior ligaments. The radial artery may be avoided; but, were it wounded, the application of a ligature to it would be attended with no difficulty. The wound is to be brought together, and the thumb supported in its natural position with soft pads placed in the palm. (See *Malgaigne, Op.* cit.) *Excision of the anterior portion of the first metatarsal bone* seems to M. Blandin advantageous, because, when the rest of it can be saved, the foot remains with a more solid support. A flap is formed at the inner side of the bone, with the base backward. The bone is exposed to the point where it is intended to divide it; sawn perpendicularly to its axis; then detached from its connexions from behind forward; and, finally, disarticulated from the phalanx. With respect to the phalanges of the other four toes, amputation is commonly preferred to excision of them; and so it is to excision of the heads of their metatarsal bones. (See *Malgaigne, Op.* cit., p. 242.) Although the *excision of the metacarpal bone of the index* and *little fingers* may easily be performed, by cutting along the outer margin of it, M. Malgaigne is probably correct in stating that such an operation, in consequence of the subsequent shortening of the finger, would leave after it as much deformity as amputation would produce, and even greater weakness of the hand. This observation is not applicable, however, to the *excision of the metacarpal bones of the middle and ring fingers*, which will still retain their connexion with the contiguous ones, and the strength of the hand be preserved. An incision is made along the dorsal aspect of the bone, by the side of the extensor tendon, which should not on any account be divided, and the disarticulation is to be begun at the knuckle. (See *Malgaigne, Man. de Méd. Opér.*, p. 233.) The removal of dead, or softened and carious portions of the carpal and tarsal bones, Mr. Liston admits, is sometimes successful; but operative interference with these, or with more extensive and formidable articulations, is not advisable, unless the soft parts be not largely involved, and the general health tolerably good. If the ligaments, bursæ, and cellular tissue are much affected, Mr. Liston considers the chance of the discharge ceasing and of the return of health entirely hopeless. Amputation above the diseased parts will still be indispensable; and, in consequence of the more reduced and deranged state of the constitution, this second operation is less likely to answer than if it had been undertaken earlier. (See *Liston's Elem.*, part iii., p. 398.) It is right to mention, however, that after necrosis of the first phalanx of the thumb and the extraction of the fragments, M. Velpeau has known the part regain its motion. If an incision were necessary for the removal of this phalanx, it should be made along the radial side of the thumb, and the metacarpal articulation, which is the looser one, being opened first, the phalanx should then be luxated outward, and dissected out. (See *Malgaigne, Man. de Méd. Opér.*, p. 231.) In a few cases, Mr. Liston has removed several of the *tarsal and carpal bones*, as practised by Mr. Dunn, of Scarborough (see AMPUTATION); in others, one, or a portion of one, with success. In one instance the greater part of the *astragalus was taken away along with the ends of the tibia and fibula*. There remained a large opening across the joint, through which a seton was passed, to promote the gradual and piecemeal discharge of the remaining portions of diseased bone. The articulation could be seen through. The seton was gradually diminished, and the aperture closed. The foot was preserved, and the leg was somewhat shortened; but the limb proved extremely useful, though the ankle retained little power of motion. Mr. Liston, as well as many other surgeons, has also trephined the *os calcis*, and *removed* large portions of it. He has likewise taken away the *cuboid bone, along with the bone of the metatarsal bone or bones* in connexion with it. In some of these cases an excellent cure followed; in others, amputation of the foot was afterward necessary. (Vol. cit., p. 400.) Examples of the *removal of extensive portions* of the *os calcis* are reported by Hey, Moreau, and M. Roux. In the North London Hospital there was a young woman, in 1835, from the outer part of whose os calcis Mr. Liston removed a considerable piece with a trephine. The case was a scrofulous caries. Some amendment followed; but the caries penetrated too far to admit of complete removal in this manner. A fine specimen of the same thing was lately put into my hands by Mr. Morton, of University College, the part having been finally amputated in the Newcastle Hospital. In one case, where the *scaphoid bone* of the carpus was dislocated by an injury, occasioned by machinery, Sir Astley Cooper successfully *removed* that bone. The rule proposed by him for any analogous case is to take away one, or even two of the carpal bones, if displaced; but, if the mischief is greater, to amputate.

I am not disposed to bestow much commendation on such an operation as the *excision of the ribs*, notwithstanding the high and respectable authorities which may be quoted in sanction of it, with the exception of its performance in cases where a sequestrum is nearly or entirely loose. The most remarkable excision of the ribs yet recorded is that performed by Mr. Richerand, in 1818, on a medical officer, who was afflicted with cancer of the thorax. The middle portion of four ribs was removed to the extent of several inches. It was also necessary to extirpate the contiguous part of the pleura, which was very much thickened, and transformed into a cancerous substance. Thus the pulsations of the heart within the pericardium were brought completely into view. The case afterward went on favourably for a time, but in the end proved fatal by a return of the cancerous disease. I scarcely need advise British surgeons not to attempt any similar operation where the disease of a rib, or, indeed, of any other bone, is the effect of a primary cancerous affection of the soft parts. Such an experiment must inevitably terminate in the return of the original malignant disease, unless the patient's accelerated death happen not to leave sufficient time for this result. These observations are directed chiefly, however, to the

particular case here specified; for, as the excision of portions of ribs has been performed by several eminent surgeons with success, I conclude that circumstances may occur in which the plan is justifiable. Not to lay any stress upon the instances of the practice in ancient times by Galen, Aymond, Sediller, Lecat, Ferrand, &c., it has been twice resorted to subsequently to Richerand's operation, and with success, by Attadini in Italy; also in the Hospitals Beaujou and La Charité at Paris, and by Dr. Mott, of New-York. The operation consists in xtending the incision through the soft parts beond the extent of the diseased portion of the rib, both in front and behind, and then, after detaching the bone from the pleura at the point where it intended to divide it first, it may be sawn through with one of Hey's saws, or, what will be more convenient, divided with a pair of cutting pliers. The divided end of the bone should then be inclined outward, and separated from its connexions, so as to facilitate the safe division of it beyond the extremity of the disease. A principal thing in the operation is to avoid injury of the pleura as much as possible.

In 1825, the *excision of the radius* was accomplished with complete success by Dr. R. Butt, of Virginia; and in 1826, M. Velpeau had a case in which he was desirous of practising a similar operation, on account of disease entirely restricted to that bone, but the patient preferred amputation. (See *Velpeau, Nouv. Elém. de Méd. Opér.*, t. i., p. 565.) An incision is made along the outer and anterior part of the radius. The edges of the wound are to be held apart, and the muscles detached from its anterior and posterior surfaces a little below its middle part, where it is most superficial; a chain-saw is to be used; a director now being introduced at the ulnar side of the bone, will serve to convey the chain-saw behind it. In the place specified, the bone is sawn through, and the two fragments carefully dissected out. If sufficient room were not obtained for the action of the saw by the longitudinal incision, a transverse one should also be made. (*Velpeau, ib.*) A strong pair of cutting forceps would divide the radius with less difficulty than a chain-saw.

In an example of *necrosis of the outer third of the clavicle*, M. Velpeau removed the scapular portion of it. Two incisions in a crucial form, and four inches long, were made, the flaps raised, the acromio-clavicular ligaments, and some parts of the origin of the deltoid and trapezius divided. The bone was then raised with a lever passed into the joint, and its detachment completed. M. Malgaigne conceives that a better plan would be to make first an incision parallel to the clavicle, but a few lines below it, and ending at the acromion, and then another shorter one at a right angle with this extremity of the first, so as to form a triangular flap. Instead of a chain-saw, the clavicle may be very safely divided with one of Hey's saws or a pair of cutting pliers, care being taken to pass a flexible copper spatula under the part.

The *sternal end of the clavicle* was removed many years ago by Mr. Davies, a surgeon of Bungay, in Suffolk, on account of its being displaced backward, and dangerously compressing the œsophagus, in consequence of the scapula being forced very much forward by a deformity of the spine. (See *Sir Astley Cooper on Dislocations.*) In this operation, a piece of leather was placed under the bone to protect the subjacent parts from the saw. The interclavicular ligament was torn through, so as to free the sternal end. The patient was alive six years after the operation, and in good health.

The *whole clavicle* affected with osteo-sarcoma was *removed* by Dr. Mott, of New-York. The tumour was of the size of two fists, and reached upward nearly to the hyoid bone and angle of the jaw. A semilunar incision, with its convexity downward, was made below the swelling, from one end of the bone to the other. Another incision was next made above the tumour, from the acromion to the external margin of the internal jugular vein. The platysma, and a portion of the trapezius having been divided, a director was passed under the bone near the acromion, and a division here effected with a chain-saw. Not being yet able, however, to displace the tumour, Dr. Mott, with the aid of a director, extended the first incision inward; and, having applied two ligatures to the external jugular vein, and cut it through in the interspace, he next divided the clavicular portion of the sterno-mastoid muscle, and found it necessary, also, to tie and divide the internal jugular vein. The subclavian vein and thoracic duct were separated from the diseased parts with the handle of the scalpel. Lastly, the great pectoral muscle, the costo-clavicular ligament, and the subclavian muscle having been divided, the disarticulation of the sternal end of the clavicle was accomplished. The bleeding required forty ligatures for its suppression. In six weeks the wound was nearly healed, and the patient afterward, with the aid of a mechanical substitute for the clavicle, retained the power of moving the limb with but little impairment.

The *excision of the scapula*, to a greater or lesser extent, has been performed on several occasions. In one instance, a considerable portion of the scapula was removed by M. Janson, on account of a tumour involving it. Two semi-elliptical incisions were made so as to circumscribe the swelling; as much skin as possible was dissected up and saved; the tumour and bone were then detached from their connexions in every direction, as low down as the fossa subscapularis. The attachments of the trapezius, supra and infra spinatus having been divided, and the portion of the bone above the spine ascertained to be sound, all the other diseased part was sawn off, and the shoulder-joint left uninjured. One more incision was necessary to expose the whole of the tumour, and facilitate its excision. The wound was altogether six inches in breadth and nine in length. The motion of the shoulder was preserved. A large tumour of the scapula was removed two or three years ago by Mr. Earle; but, as the disease returned, Mr. Skey removed it a second time, together with the greater part of the scapula. The disease, however, being of a malignant character, again returned, and proved fatal. Several cases of this description have been lately met with in the hospitals of this metropolis. One was in the North London Hospital, under Mr. Liston. I heard of another in the Westminster Hospital.

Excision of the whole of the fibula, with the exception of its head, was performed by M. Scutin. The particulars are contained in M. Malgaigne's Manual. Many arteries required ligature, and, among them, the posterior tibial. The external popliteal nerve was also divided. As the tibia was slightly affected, the cautery was applied to it. In two months the wound was healed, and

in four the patient could bear nearly as well on this leg as on the other.

In the articles Amputation and Gunshot Wounds, I have noticed the excision of the upper head of the humerus; and in that on Anchylosis some account is given of Barton's *excision of the head and neck of the femur*, an operation to which an allusion is made in the writings of C. White, of Manchester, and which has been performed by Sir Benjamin Brodie, Mr. Anthony White, and in Germany by Oppenheim. Sir Benjamin Brodie lately informed me that his patient died some time afterward of phthisis. I believe the case was one in which it was suspected that the disease was restricted to the head of the femur. My friend, Mr. Anthony White, has favoured me with the following particulars of the case in which he performed the operation: John West, a twin of delicate make, was born and resided in Westminster. When between four and five years old, he suffered from scrofulous inflammation in the left hip-joint, which passed through the stages of elongation, dislocation, and subsequent retraction, and the femur was finally lodged in a very high position, on the dorsum of the ilium. "About three years subsequent to the commencement of the disease, and when he was about eight years old, I first saw him. He was much emaciated; several abscesses had formed during this period around and over the diseased structures, leaving many fistulous openings, through which the probe easily detected the surface of the displaced bone to be in a state of caries, and several small exfoliations had occurred from the ilium, ischium, and os pubis, over which bones abscesses had formed. In the progress of the disease, the knee of the affected limb had become inverted, and firmly imbedded on the lower and inner part of the opposite thigh, from which position it could not be removed, and every attempt to do so was accompanied with exquisite pain. All farther attempts, therefore, were abandoned, and the limb left undisturbed. He had now lain nearly three years on the opposite side, with the body considerably incurvated, and without the power of changing his position. A profuse and debilitating discharge was constantly issuing from the numerous apertures leading to the carious surface of the displaced bone. In other respects, the health of the boy was tolerably good. Reflecting on this poor boy's case, it was evident that, unless the knee could be removed from its firm lodgment on the opposite thigh, he must remain in the position above described during the remainder of his life, and this could only be effected by removing the upper portion of the femur, which, from its trifling mobility, induced the belief that a firm union was taking place between its under surface and that of the ilium, with which it had been long in contact, and the form of which was very apparent under the thin integuments with which it was covered. Considering also, that, as an entire destruction of every texture which forms a healthy joint had taken place, no danger could be reasonably entertained from meddling with parts in their existing condition, and attempting the removal of the head of the displaced bone; and, farther, that the strength of the boy, from the profuse discharge kept up by the caries of the bone, was never likely to be restored, I was induced, after mature reflection, to propose an operation for the removal of the upper part of the femur as far as it should be found in a state of caries, which, from examination with the probe, appeared to extend probably a little lower than the great trochanter. If this could be accomplished, it would set free the lower portion of the bone imbedded on the opposite thigh, and enable me to draw outward the whole limb, and possibly place the boy in a condition equally favourable with those cases where a similar disease had occurred, and in which a compensatory joint is formed, on which locomotion is effected with or without the aid of a crutch. I proposed to divide the integuments covering the bone, beginning above its head, which was easily detected, and carry it downward in the centre as low as might be found necessary, and separate the soft parts from the shaft of the bone towards either side. I then proposed to divide the bone at the lowest exposed part with a small saw, and to elevate it with a lever from the dorsum of the ilium. I hoped that the wound would heal over the divided end of the bone, which (now being set free) might be brought into a straight line, and which motion would incline deeply into the wound the end of the divided bone. The wound itself was to be treated as a common incision, with adhesive plaster and bandage, and rigid quietude. My colleague, the late Mr. Morel, saw the case, concurred in the proposition, and offered to be my assistant. The late Mr. William Smith, member for Norwich, and to whom the mother of the boy was well known, informed the late Sir E. Home of the proposed operation. The boy, at his request, was conveyed to St. George's Hospital; and, after an examination of the case with his colleagues, a written document, signed by him and them, was given to the mother of the boy, declaring that the contemplated operation would not only be useless, but impracticable, and most likely, if attempted, be attended with loss of life. I was not present at this consultation, and only knew of it by being shown this document or protest by the boy's mother. Of course, with such a published declaration, I abandoned the case altogether. After the lapse of some months, Mr. Travers, while attending at Mr. Smith's house in the city, to which the boy West had been removed with his mother, was requested to look at him; and being told of the proposed operation by the mother, who was an exceedingly intelligent person, at once saw and understood the principles and plan of the proposition. He subsequently wrote me a note, expressing his entire concurrence in the measure, and kindly offered to assist me in the operation, notwithstanding the formidable protest which had been issued shortly before. Glad of the concurrence of so distinguished an individual, and my own opinion as to its practicability being unchanged, I gladly accepted of the offer. A lodging in Westminster was procured for the boy and his mother. We met in consultation, and an early day was fixed for the operation.

"In April, 1821, we met; and the boy being placed on a table of convenient height, I proceeded to divide the integuments covering the bone, carrying the incision from an inch above the head, directly along the middle line of the bone, about two inches below the greater trochanter: this was completed at one incision down to the surface of the bone. The integuments were dissected inward and outward, thus leaving the bone entirely bare a little lower down than the lesser trochanter, which was distinctly visible. A spatula was now placed under that part of the bone which was intended to be sawn through, so as to protect the structures under

neath. This was readily accomplished. A smaller spatula was then introduced into the space made by the saw, and used as a lever to raise the bone, which, with a little dissection, was removed from the dorsum of the ilium. No vestige of the acetabulum remained, neither was any caries of the ilium discovered. The thigh was now readily brought into a straight line, and the knee liberated from its position on the thigh. The wound was closed by adhesive plaster, and no portion of the bone was left exposed. Splints and an eighteen-tailed bandage were applied, and the limb placed in the straight position. The boy bore the operation well, and not more than two ounces of blood were lost. The head, neck, and trochanters were very apparent, the caries being superficial, and not extending lower than the lesser one. The case proceeded very favourably, and in a few weeks every sinuous opening had healed, and also the incision made in the integuments. The patient rapidly acquired strength and flesh. At the end of two months I began to examine the parts, to ascertain if they had formed any attachment to the surrounding structures; and, on attempting to move the limb in different directions, I discovered that the boy himself had the power of raising the thigh upward, which power gradually increased, and, finally, a very extensive motion was accomplished by the spontaneous action of the muscles. I now proceeded to examine whether he could bear pressure upon this foot without inconvenience, which was the case at the expiration of about four months from the time of the operation. He was put on crutches, and in a very short time could bear considerable pressure on the foot, and at the end of a year he could walk on a high stirrup without his crutches. Finally, it was clearly ascertained that a new and useful joint had been formed, the boy being enabled to walk several miles without the aid of a crutch or stick. He acquired great latitude of motion, except in rotating the thigh outward, and separating the thigh laterally outward. He was apprenticed to a lady's shoemaker, and five years after the operation he became phthisical, and died of diseased lungs in the Westminster Hospital. The limb was removed with half the pelvis, and is in the possession of the Royal College of Surgeons; but the parts have not yet been examined, in order to ascertain the changes which had so usefully been employed in giving almost a perfect joint as a compensation for the original. The shaft of the femur appeared to have lost the power of farther elongation; for, on frequent admeasurement during the life of the patient, it was discovered not to have increased in length. Probably the fact is not generally known that bones do not increase in length after the amputation of their heads."

EXCISION OF THE SUPERIOR MAXILLARY BONE.

In the article Antrum, certain states of disease of this cavity are noticed, in which the only chance of cure depends upon the entire removal of the upper jaw-bone itself. I allude to osteo-sarcomatous, fibrous, and other tumours, which originate within the antrum, and by enlargement produce such an impairment of, and pressure upon the surrounding organs and textures, as must ultimately prove fatal unless a bold attempt be made to extirpate every part of the osseous texture, serving as a place of attachment to the swelling. Merely excising the alveoli and front of the antrum, and then attacking the tumour with the knife, cautery, or caustic, generally fails. Baron Dupuytren was led to suspect, that by the excision of the upper jaw-bone its total extirpation might be performed with a successful result. He was induced to form this opinion from the consideration of the examples on record, where the patients recovered after most severe mechanical injuries of the face and necrosis, occasioning the destruction of the bone. Camper mentions a case in which the whole of the bone came away in consequence of necrosis, and the patient was cured. Acoluthus is stated, indeed, to have actually removed the upper jaw-bone for a tumour of the face as long ago as 1693. Bidloo and Desault also anticipated Dupuytren in the belief that the upper jaw-bone might be successfully extirpated, though they never undertook the operation themselves. The bulletins of the Faculty of Medicine at Paris prove that Dupuytren removed, at all events, the greater part of the bone in 1824; but, as MM. Pillet and Gensoul contend, probably not the whole of it. M. Velpeau states that, in 1824, Mr. Rogers, of New-York, removed both upper jaw-bones as far back as the pterygoid processes, and this without making scarcely any incision through the lip. (See *Nouv. Elém.*, t. i., p. 549.) In 1826, Mr. Lizars also advocated the removal of the whole of the upper jaw-bone, and he performed the operation with success in 1827, 1828, and 1830. In May, 1827, M. Gensoul, surgeon to the Hôtel Dieu at Lyons, removed every part of this bone, together with the whole of the palate bone, on account of a fibro-cartilaginous tumour, and the patient got completely well. (See *Velpeau, Nouv. Elém. Méd. Opér.*, t. i., p. 247; *Jh. Gensoul, Lettre Chir. sur quelques Maladies Graves du Sinus Maxillaire, &c.*, p. 18, 8vo, Paris, 1833.)

In this work M. Gensoul states, that several years previously he had known patients die of very tedious operations undertaken for the removal of cancerous and other tumours of the antrum. Reflecting on the fate of these unfortunate individuals, he was led to conclude that others labouring under similar diseases might be cured by an operation which consisted in freely denuding the antrum and upper jaw-bone, so as to be able to divide the sound parts instead of meddling with the diseased ones, and of searching for the precise limits of the disease in the midst of blood and the remains of the affected textures. In short, he was induced to think that the same principle should be acted upon in this operation as is followed in others undertaken for the extirpation of cancerous tumours in general.

If the face of the skeleton be examined, it will be seen that the upper maxillary bone is fixed to the others only at three principal points: 1. By means of its nasal process, and at its connexions with the os unguis and ethmoid bone. 2. By means of the orbitar process of the malar bone as far as the spheno-maxillary fissure. 3. By means of the connexion of the upper jaw-bone to its fellow, and to the palate bone. There is, indeed, a point of contact behind with the pterygoid process and palate bone; but this readily gives way on depressing the upper jaw-bone towards the mouth. In attacking these different points, no large vessel is injured; the trunk of the internal maxillary artery generally escapes, and, if wounded, may be readily tied, as was exemplified in the removal of the whole of the superior maxillary bone, performed by Mr. Liston in the North London Hospital on the 27th February, 1836. If the hemorrhage during the oper-

ation were to be greater than calculated upon, the carotid artery might be compressed against the transverse processes of the cervical vertebræ. As for nerves, the only one of consequence necessarily divided is the superior maxillary; but it may be easily cut through before the bone is displaced, and then the laceration of it avoided, if judged advisable. This proceeding is strongly advocated by M. Gensoul; but in the operation which I have seen performed, no preliminary division of the trunk of this nerve was practised, yet no ill consequences were the result.

The patient should be seated in a chair, with his head inclined backward, and supported on the breast of an assistant. One of the incisor teeth is to be extracted at the place where the division of the bone is to be effected below. An incision is now to be made from the inner canthus of the eye down to the upper lip, which is to be cut through opposite the canine tooth; and the incision may then be made from a point five or six lines to the outer side of the external angle of the eye down to the termination of the first. This will leave the parotid duct safe below it. The flap is next to be raised up as far as the lower border of the orbit. This plan is more simple and less disfiguring than that of M. Gensoul, who, after the first incision has been made, makes a second from the level of the nostril to a point about four lines in front of the lobe of the ear; and then a third, extending from a point five or six lines behind the external angular process of the os frontis down till it meets the termination of the second cut. The quadrilateral flap thus formed is then reflected on the forehead. M. Velpeau prefers an incision commencing at the commissure of the lips, and carried outward, and then upward towards the temporal fossa. This would not, however, expose the bone sufficiently for the section of its nasal process, for which purpose the perpendicular cut, from the inner canthus down to the upper lip, is very necessary. When the tumour is large, the circular sweep of the knife, as advised by M. Velpeau, and long ago practised by surgeons in this country, has advantages. The bone having been denuded, the next step is to divide the connexion of the malar bone with the external angular process of the frontal, and immediately afterward the zygomatic process of the malar bone. These excisions are best accomplished with Liston's cutting forceps, which should have long powerful handles, a construction found in the North London Hospital to answer better than jointed-handled ones, which cannot be opened so wide, and have a tendency to slip off the bone instead of cutting it. The greater power with which they shut does not, therefore, seem to Mr. Liston to compensate for the inconvenience referred to. At all events, any additional power required can be obtained by simply lengthening the handles.

The next thing is to divide the nasal process of the superior maxillary bone, and the connexion of the latter bone with the os unguis and os planum. For this purpose, one blade of the forceps is put within the orbit, the other within the nose, and the section accomplished.

This having been effected, and a cut made under the lower part of the palate, the upper jaw-bone is divided with the same instrument at the place where the incisor tooth was extracted, together with the palatine process and palate-bone at the symphysis.

The bone being next pressed downward, the slight connexion with the pterygoid process through the medium of the palate-bone gives way, when the upper jaw-bone, including the whole of the antrum and disease originating in it, is easily dissected out. The flap is brought down, and the wounds united with the twisted suture, aided with narrow strips of adhesive plaster. Mr. Liston prefers, as less irritating, strips of oiled silk smeared with a solution of isinglass in brandy. These strips he does not usually remove till the wound is healed. The straight steel needles which he employs for the twisted suture, and the eye-ends of which are tipped with red sealing-wax, and the points cut off with pliers directly after their introduction, are removed within the first forty-eight hours, leaving the many-twisted silk to come away as soon as it loosens.

The following is Mr. Liston's description of the operation: To expose the bone, the cheek is divided from the angle of the mouth to the origin of the masseter, and a second incision made from the inner canthus to the edge of the upper lip, near the mesial line, detaching the ala of the nose from the maxillary bone. The flap of the cheek thus formed is dissected up, and the nasal process of the maxillary bone and the body of the os malæ are divided with a saw or with strong cutting pliers. An incision having been made through the covering of the hard palate, near the mesial line, a small convex-edged saw is applied to the bone, and the alveolar process is cut through with the pliers, after extraction of the middle and lateral incisors. The bone is then pulled downward and forward, and its remaining adhesions separated by means of the knife or pliers. During the progress of the operation, the cut branches of the facial and temporal arteries are commanded by ligature or pressure, and the violence of the hemorrhage is moderated by pressure on the carotids. After removal of the bone, the deep vessels, branches of the internal maxillary, are secured either by ligature, or by firm pressure with charpie or dossils of lint. The facial flap is replaced, brought together over the charpie, by which the cavity is filled, and united by interrupted or convoluted suture. (See *Liston's Elem.*, part ii., p. 160.)

In the examples of this operation which I have seen, any preliminary ligature of the common carotid artery would have been totally unnecessary. In one instance the internal maxillary was cut, but secured with the greatest facility. In a case operated upon by Mr. Liston in the North London Hospital, not a single ligature was necessary.

It is an important object to prevent, as much as possible, the blood from flowing towards the throat in the early part of the operation: hence the advantage of the sitting posture, and of Gensoul's plan of beginning with the division of the cheek-bone or zygoma, before the nasal process of the upper jaw-bone itself is attacked.

EXCISION OF LOWER JAW-BONE.

The practicableness of this operation was long ago evident enough, from cases in which the greater part of the bone had been torn away by gunshot injuries, or where it had exfoliated from necrosis. Boyer relates an instance in which it was torn away by machinery, and Wepfer quotes a case where it was amputated in his time. Mr. Anthony White, surgeon to the Westminster Hospital, removed at Cambridge a considerable portion of the bone for an osteo-sarcoma many years ago. Unfortunately, the case was not pub

lished, so that the revival and execution of the operation are generally referred to Dupuytren, who in 1812 performed his earliest excision of the body of the lower jaw-bone. The parts removed weighed a pound and a half; the bone was affected with exostosis, caries, and necrosis, softened in several places, and combined with a hard fibrous fungus. The patient recovered, and was in perfect health twenty-one years after the operation. (*Dupuytren, Clin. Chir.*, t. iv., p. 628.)

Subsequently to the year 1812, the operation has been frequently repeated by Dupuytren, Dr. Mott, Richerand, Lallemand, Delpech, Roux, Cusack, Martin, Gerdy, Magendie, Cloquet, Wardrop, Lisfranc, Warren, Gensoul, Græfe, Walther, Wagner, Randolph, Liston, Lawrence, P. Crampton, Velpeau, &c. By M'Clellan, Walter, and Græfe, nearly the whole of the bone has been taken away. By many other operators, disarticulation has been performed at one of the condyles. (See *Cusack* in *Dublin Hospital Reports*, vol. iv., p. 13; *Liston's Elem.*, part ii., &c.)

The method of performing the operation varies according to the extent of the disease. To expose the tumour, and allow the body to be readily divided, there must necessarily be a free division of the soft parts. Previously, also, to fixing upon the plan of operation, the extent of the disease must be correctly ascertained. (See *Liston's Elem.*, part ii., p. 224.) When only *the central portion of the body of the bone* was to be *removed*, the following was Dupuytren's plan: the patient is seated, and his head held steady against the breast of an assistant, who is to stand behind him, and, if necessary, make pressure on the facial arteries. The surgeon, standing in front of the patient and on his right side, is to take hold of the right portion of the lower lip with his left hand, while an assistant takes hold of the left portion. In this way the lip is rendered tense, and separated from the other. With a common scalpel an incision is then made completely through it, from above downward to the base of the jaw. The next thing is to extend the wound through the skin and cellular tissue from this point down to the prominence of the os hyoides. Thus two flaps are produced, each of which is to be dissected up as far as the extent of the disease requires, with the knife kept close to the bone, so that the facial arteries may not be wounded. The exact places having been ascertained to which the saw is to be applied, a tooth on each side must be extracted. The operator then taking a fine metacarpal saw, or one of Hey's, goes behind the patient, in which position the saw can be employed without any risk of its extremity being pushed against the palate. If requisite, the nose and upper lip may be protected with a piece of pasteboard. But, according to my observations, the best plan is only to make a groove, or partial division of the bone with the saw, and then to complete the section on each side with the cutting pliers, which expedite the business very considerably, and with no risk of injury to the contiguous parts. The bone having been cut through on each side, the surgeon takes hold of the portion about to be removed with his left hand, and, while it is inclined forward, he introduces a straight bistoury from below upward close behind it, and detaches it from the soft parts to the right and left, keeping the edge close to the bone. An assistant takes care to keep the tongue out of the way with a spatula or the handle of a director. The vessels are now secured, the ends of the bone approximated to one another, and the flaps of skin united with sutures; care being taken to leave a small portion of the wound open below for the insertion of a bit of charpie or lint, and as an outlet for the discharge in the event of matter being formed.

If the portion of bone to be taken away were so extensive as to require the excision of a part of the integuments, Dupuytren made two incisions, one in each side of the lip, which were extended down so as to meet the os hyoides, and form together one in the shape of a V. When a perpendicular cut will not suffice, on account of the extent of the disease, it may be converted into a crucial wound by making an incision along the base of the jaw.

One danger attending the operation is the retroversion of the tongue into the pharynx as soon as the attachments of the genio-glossi muscles behind the symphysis have been cut. In this state the tongue presses the epiglottis towards the glottis, and the patient is in imminent peril of suffocation. Indeed, in one case, M. Lallemand would have lost his patient had he not instantly performed tracheotomy. Hence Delpech, before he divided the muscular connexions of the tongue behind the symphysis, used to seize the extremity with a double tenaculum, which was then intrusted to an assistant; and afterward, in applying the sutures, he passed the thread of one of them through the frænum of the tongue and the skin together; if the interrupted suture were employed, or, supposing the twisted suture to be preferred, the ends of the thread, passed through the frænum, were twisted round the pins. In one case Delpech introduced a piece of gold wire through the apex of the tongue, and fastened it to the contiguous teeth. The wire soon cut its way out, leaving a sufficient adhesion. In few instances, the circumstances of the disease may be such as to make it necessary to remove only a portion of the depth of the bone.

As the retroversion of the tongue, though not constant, is always a possible event, I concur with Malgaigne (*Man. de Méd. Opér.*, p. 255) in the prudence of attending to the advice delivered on this subject by Delpech, or else of taking care not to cut through the insertions of the genio-glossi muscles until the possible displacement of the tongue has been guarded against.

In the *excision of the whole of the horizontal portion of the lower jaw-bone*, one plan consists in making an incision along its base, and extending it a line or two beyond its angles. A large flap is then dissected up, and turned over the face. The bone is sawn on each side beyond the limits of the disease, and then detached from the soft parts which are connected with it behind, with the precautions and according to the directions above particularized.

If the disease were to extend high up in the rami, an incision should be made along the posterior edge of each ramus so as to meet the extremities of the first wound.

Another method, specified by M. Malgaigne, is easier than the foregoing. After the horizontal incision has been made, a perpendicular one is made completely through the lower lip, and carried down in the middle line till it meets the horizontal wound. Both the lateral flaps are then dissected up.

In the *excision of one half of the horizontal portion* several methods are adopted. In one, preferred by several British surgeons, and also by J

Cloquet, a horizontal incision is begun at the commissure of the lips, and terminates at the distance of one or two lines beyond the ramus of the jaw. To this first incision are added two vertical ones: one descending from the border of the lip to the base of the bone; the other, taking a parallel course, descends behind the ramus to a point a few lines below the angle. The flap is dissected from above downward; the soft parts are next detached from the inner surface of the jaw, and, lastly, the bone is sawn through. In the latter proceeding I particularly recommend Hey's saw, or a small metacarpal one, for making a groove in the bone, which can then be divided with the cutting pliers at one stroke, as practised by Mr. Liston, and always demonstrated by me in the Lectures on Operations at the London University.

Mr. Liston has likewise expressed himself as follows in favour of one method, in which the flap is made from above downward: "The cheek may be divided (says he) by passing through it a long narrow bistoury close to the anterior edge of the masseter muscle, and carrying the instrument forward, and through at the angle of the mouth. From each extremity of this incision another is made downward, the anterior one inclining forward, the other backward. By reflection of the flap thus formed, the bone is exposed more easily, rapidly, and perfectly than by the former mode of incision, in which the flap is made by a semilunar incision along the base of the jaw." (See *Liston's Elem.*, part ii., p. 225.)

In the plan adopted by Dr. Mott, of New-York, *two flaps are formed*. A curved incision is made, with its convexity downward, from a point in front of the ear, and on a level with the condyle, to the vicinity of the chin, below the commissure of the lips. The upper flap is raised and reflected on the face. A second incision, descending from the upper end of the first to the angle of the jaw, enables the surgeon to form a lower flap. The bone is sawn through, first in front, and then behind, as high up as the circumstances of the case require. If above a certain point, Dr. Mott recommends the inferior maxillary nerve to be cut through before the bone is drawn outward, and the lingual branch of the fifth pair to be carefully avoided.

A *third method*, which has the names of Cusack, Lisfranc, Liston, Malgaigne, &c., in its favour, consists in making, first, a vertical incision through the lip down to a point below the chin, and then a horizontal cut, extending from the first along the base of the jaw to two lines beyond its angle. The flap is then dissected off the tumour, in the direction from below upward, and reflected on the face. The bone is then sawn through in front and behind, and the flap united with sutures. I am of opinion with M. Malgaigne, that this plan is more simple than the others; no lodgment of pus is likely to follow it; and the scar will produce but slight disfigurement. I recommend, however, the front portion of the bone to be divided before the posterior part of it, as facilitating the safe detachment of the mylohyoideus and other parts connected with its inner surface.

One method, described by Mr. Liston, is a modification of the foregoing: "If the tumour is included between the lateral incisor tooth and last molar, on the same side, these teeth must be extracted to permit division at these points. A semilunar incision may then be made along the base of the jaw, the horns of the incision pointing upward, and passing over the spaces which were occupied by the extracted teeth. The flap is dissected up, and the membrane of the cheek divided along the line of the incision. The bistoury is then carried along the inside of the bone, so as to divide the membrane of the mouth, and separate the attachments of the muscles. The tongue is pushed aside, and a copper spatula placed under the jaw at the part to be divided, in order that the soft parts may not be injured during the sawing. A small narrow saw, or one commonly known by the name of Hey's, is applied to the bone at the points where the teeth were extracted, and by a few motions of this instrument a notch is made of no great depth; a pair of strong cutting-pliers are placed in the track, and by them division of the bone is accomplished with equal neatness and much more rapidly than if the use of the saw had been continued. The pliers should be strong in every point, and the handles long, to afford the advantage of a powerful lever." The chain-saw, he says, is not to be depended upon, and is slow in its operation. (See *Liston's Elem.*, part ii., p. 224.)

A *fourth plan*, described by M. Malgaigne, may be applicable where the disease extends more in the direction backward than forward. In such a case, perhaps it may be sufficient to make a semilunar incision along the posterior border of the ramus and the base of the bone, from the ear to the chin. Thus only one flap would be formed, and no cicatrix would be seen on the face.

M. Malgaigne lays it down as a maxim, that, in making the flaps in any of these operations, the skin and cutaneous muscles should alone be divided, and that the masseter should be cut through, and removed at the same height as the bone itself.

The facial artery is readily secured. All those operators who have had recourse to the ligature of the carotid artery as a preliminary measure, have subjected their patients to a very needless proceeding.

Even in the *excision of one half the lower jaw-bone at its articulation* with the temporal bone, the ligature of the carotid artery is quite uncalled for. One plan consists in making an incision along the base of the jaw; a second one is then made perpendicularly through the lower lip down to the first; and a third begins at the zygoma, and extends behind the ramus. The flap is raised, and the fore part of the bone sawn through. The soft parts are then detached from its inner surface, and the tendinous attachment of the temporal muscle to the coronoid process cut through from within outward. Lastly, the disarticulation of the condyle is effected: for this purpose, the external lateral ligament should first be divided; and, while the bone is depressed and twisted, in order to render the capsular ligament tense, the latter part may either be cut through with scissors, as recommended by M. Malgaigne, and then the probe-pointed bistoury used, or it may be divided at once, together with the external pterygoid muscle, by means of the probe-pointed bistoury kept close to the highest part of the inner side of the condyle, so as to leave the internal maxillary artery safe at the inner side of the neck of the bone. A great deal of the safety of this operation will depend upon the edge of the knife being kept close to the inner surface of the bone, so that the lingual branch of the fifth nerve may be left uninjured, and, upon attention being paid to the directions given for the disarticula-

tion, which, after the insertion of the temporal muscle has been divided, is greatly facilitated by depressing the anterior part of the bone forcibly, and twisting the condyle itself. The hemorrhage will be chiefly from the facial, dental, and branches of the temporal and internal maxillary arteries.

Instead of making the flap exactly in the manner above described, I prefer making, first, the anterior perpendicular incision, and then another, beginning a little way in front of the lobe of the ear, extending down along the posterior border of the ramus, and then forward along the line of the base till it meets the lower termination of the first wound. This is more simple, and enables the surgeon to get more readily at the external lateral ligament.

In the horrible operation of extirpating the whole of the lower jaw-bone, the incision should extend from a point a few lines in front of the lobe of one ear, down the posterior edge of the ramus along the whole base, from one angle to the other, and then up to a point a few lines in front of the lobe of the other ear. Care having been taken to prevent retroversion of the tongue, and the front portion of the flap raised, the soft parts behind the symphisis should be cut, and the bone sawn in this situation. Then the rest of the vast flap is to be raised on each side, and each half of the bone to be removed according to the foregoing directions.

BONES, PATHOLOGY OF.

As a living texture, that of the bones is subject to many of the diseases which affect other parts endued with vitality, and in which the functions of circulation, innervation, absorption, and nutrition are continually going on. Thus it is liable to atrophy, hypertrophy, inflammation, suppuration, a change resembling ulceration, and another like mortification of other parts. The nerves, it is said, have never been demonstrated in the osseous texture; yet, if it be the seat of pain, our judgment must infer the existence of what may not be discernible by the eye. M. Sanson very aptly compares the organization of bone to something between that of an organic and that of an inorganic body, its vitality being necessarily obscure, and correspondent to its constituent elements. The organic actions seem, indeed, to be carried on in it with greater difficulty, the more the earthy matter in it predominates over the animal part. Thus, in children, irritation, inflammation, and every action in the osseous texture are quicker than in old persons, because the bones in early life contain a greater proportion of animal matter than at a later period, when the phosphate of lime is more abundant. However, even in children, and still more conspicuously in adults and old persons, the diseases of the bones are generally marked by a slowness of character which has attracted the notice of all pathologists. Many weeks are required for the completion of a provisional callus, and nearly a twelvemonth for that of a definite one; while a few days, and often a few hours, will suffice for the union of the wound of the soft parts. In consequence, also, of the inferior, or inconsiderable connexion of the bones with the nervous system, they frequently appear to inflame and undergo disease, without involving the rest of the system in any sympathetic disturbance, till the irritation is propagated to the surrounding parts, or suppuration comes on. As M. Sanson observes, a necessary consequence of these facts is, that therapeutic means, even those of the most energetic kind, frequently have but little power over affections of the osseous tissue; and, if they prove effectual, it is not till after a long perseverance with them. (See *Sanson*, in *Dict. de Méd. et de Chir. Prat.*, t. xii., p. 308.) See ANTRUM, CANCER, CARIES, EXOSTOSIS, FRAGILITAS, JOINTS, MOLLITIES, NECROSIS, OSTEO-SARCOMA, OSTEITIS, PERIOSTITIS, RICKETS, SPINA BIFIDA, STUMPS, TREPHINE, VENEREAL DISEASE, and VERTEBRÆ.—C.]

[BONE, ATROPHY OF. *Obs. on some of the Forms of Atrophy of Bone, by Thomas Blizard Curling.* Local atrophy is generally the result of pressure or friction, as exemplified in the effects of aneurism and other tumours on the bone, and in the change taking place in the size and shape of the head of the dislocated humerus, if not reduced. Of such alteration there are some excellent specimens in University College Museum. Mr. Curling notices also the local atrophy of bone from mechanical injury, and refers to the two thigh-bones figured by Cheselden in his *Osteographia*, taken from the body of a soldier who had been shot in the right groin, and died soon afterward of dropsy. The right femur is represented as much wasted, and to have been less than half the weight of the other.

The author likewise adverts to the atrophy of bones consequent to a suspension of their functions, and to that induced by deprivation of the nervous influence, as sometimes exemplified in cases of injury of the spinal chord. Mr. Curling adduces instances of these facts, and refers to a case recorded by Mr. Travers, in which the union of a fractured leg, that was paralyzed from a fracture of the lumbar vertebræ, failed to proceed, while a broken humerus in the same patient united perfectly in the usual period. (*On Constitutional Irritation*, vol. ii., p. 436.)

Although the ligature of the femoral artery in a fracture of the leg complicated with hemorrhage is well known not to interrupt the nutrition of the bone or the union of the fracture (see FRACTURES, and *Travers*, *Op.* cit., p. 436), yet it appears from Mr. Curling's investigations that, if the supply of blood to a bone by its nutrient artery be obstructed, a species of atrophy will ensue. Thus, in the thigh-bone, if fractured below the entrance of this artery, the walls of the portion of such bone below that point will be found thinned, and the cancelli expanded. Such change, however, is not observed in bones recently fractured, nor in those long united, nor in bones fractured during the period of growth. Mr. Curling concludes with some interesting remarks on fractures of the neck of the femur. (See *Med. Chir. Trans.*, vol. xxi.)—C.]

[BRONCHOCELE. Scarpa believed that the thyroid gland was never primarily affected with true scirrhus, maintaining that the disease was always consecutive to cancer, or scirrhus of the tongue, œsophagus, parotid or submaxillary gland. Dr. Sacchi relates a case, however, proving that on this point Scarpa was incorrect; and he also details an instance of fungus hæmatodes of the thyroid gland. Of this last disease there are at least two specimens in the Museum of University College.

Besides the forms of goitre already noticed, there is another, sometimes termed *aneurismatic*, and consisting of an extraordinary development of the thyroid arteries and their branches. Every point of the tumour has a strong pulsation, not, however, like that of an aneurism, but giving a

sensation as if the blood were flowing very rapidly into numerous vessels, with an obscure buzzing noise or tremulous murmur, which is more distinct over the thyroid trunks. I think a case of this description was once shown to me by Mr. Pilcher. In two cases recorded by Dr. Sacchi, the tumours had existed many years, and begun during the efforts of parturition.

Notwithstanding the numerous cures of bronchocele accomplished by means of iodine, the plan fails in many instances. As Dupuytren observes, the disease depends on different causes: sometimes it is a simple hypertrophy; sometimes a scirrhous degeneration; and on other occasions it is composed of cysts filled with matter of different kinds. Iodine cannot answer equally for so many affections of diverse character. (*Clinique Chir.*, t. iv., p. 467.) According to Dr. Sacchi, iodine is chiefly useful in the hypertrophic and scrofulous forms; less so in the lymphatic; and perfectly ineffectual against small, isolated, hard goitres. The best mode of using iodine seems to Dr. Sacchi to be friction, with an ointment of hydriodate of potass, continued from one to several months.

When a seton was passed through the thyroid gland, Dupuytren already noticed a copious discharge of venous blood; but he found it soon stop on desiring the patient to make full inspirations, and applying cold water and moderate pressure. (See *Clinique Chir.*, t. iv., p. 470.) Dupuytren would not have the seton looked upon as capable of curing every bronchocele. Of course, it will produce no favourable change in the scirrhous degeneration of the thyriod gland; but, in cases of hypertrophy, cysts, and hydatids, where iodine and other specifics frequently fail, the disease will be more likely to yield to the seton. (*Ib.*, p. 471.)—C.]

C.

[CÆSAREAN SECTION. According to Bayle, Aurelia, Cæsar's mother, was living at the period when that warrior invaded Britain, so that, if he were taken out of the womb by this proceeding, the life of the mother was also saved. Although the etymology and first practice of the Cæsarean operation are points involved in obscurity, its great antiquity is generally admitted. Mr. Crosse has lately adverted to some recent instances in which the Cæsarean operation was performed "in a majority of the conditions which may demand it: for narrow pelvis, tumours in the uterus or vagina, extra-uterine conception, rupture of the uterus, and sudden death from apoplexy and other causes. The operation (says he) has also been performed, and with success, in the leading countries of the world. In England we have a single and most critical example of its success by Mr. Knowles, of Birmingham; and in America, Professor Gibson has been the first to save the life of both patient and child by this intrepid proceeding. The most frequent examples are to be found in the publications of France and Germany; and I have grounds for stating that on some occasions the operation has been resorted to where there seemed to be scarcely a hope of any good result, or determined on when not absolutely called for, or neglected still more often where obviously applicable, not only because calculated to avoid protracted suffering, but to afford a chance of saving life. Rupture of the uterus seldom calls for ventro-section. Among the numerous cases of this accident, no less than thirty-four, related by Dr. Collins, there is scarcely one in which the operation could have been undertaken with propriety. The recovery of two patients after rupture of the uterus in Dr. Collins's practice, and under the most unpromising conditions, should impress the lesson of not despairing on the occurrence of so formidable an accident." (See *J. G. Crosse* in *Prov. Med. and Surg. Trans.*, vol. v.)

From a statement made by Baudelocque, it appears that the Cæsarean operation had been performed twenty-four times with success between the year 1750 and the beginning of the present century; and, according to M. Velpeau, even without reckoning Lauverjat's cases, which are incontestable, it has also been practised with a favourable result twice at Nantes, by Bacqua, on the same woman; once at Aix, by M. Le Maistre; once by M. Dariste, at Martinique; once at Dahlen, by Vonderfuhr, in 1823; once in May, 1827, in the Hospital of Florence; twice by Schenck; once by Bulk; once by Graefe; once by Burns; and once more, quite recently, in the colonies. Let not practitioners, however, underrate the true danger of the operation; for, as M. Velpeau justly observes, no doubt every successful case has been brought before the public, while many unsuccessful ones have been kept out of view. His belief is, that at least half of the operations have had a fatal termination. (See *Nouv. Elém. de Méd. Opér.*, t. iii., p. 677.)

Ruth, a surgeon in Upper Silesia, performed the Cæsarean operation successfully in a case of extra-uterine pregnancy of some years standing, during which period the woman became pregnant in the usual way, and was safely delivered. (See *Graefe and Walther's Journ.*, part iii., vol. vi.) The particulars, which are well deserving of the attention of obstetric practitioners, may also be found in one of our own periodicals. (See *Edinb. Med. and Surg. Journ.*, vol. xxiii., p. 429.)—C.]

[CÆSAREAN OPERATION.

When the former edition of this Dictionary was published, it was correctly stated that in England this operation had never been successful, though it had been performed thirty times. The only instance of its performance in America at that period was the case reported by Dr. Richmond, of Newton, Ohio, in which the mother was saved. Since then, however, Professor Gibson has been the instrument of conferring exalted honour upon American surgery by the successful performance of this splendid operation, and repeating it about two and a half years afterward upon the same patient, and in both instances he has completed his triumph by saving both mother and child, a result which has never been attained before in the United States. Indeed, there is but a single instance of a similar result in Great Britain, and that by Mr. Knowles, of Birmingham, recently reported.

The circumstances of this intrepid proceeding

of Professor Gibson, which is an honour to his surgical science and skill, together with the history of each operation and its results, will be found detailed with great particularity in his late edition of the Institutes of Surgery. For the purpose of discriminating this operation from gastrotomy, which is sometimes necessary for removing an extra-uterine fœtus, he denominates it hysterotomy, or Cæsarean section. The enduring interest which these operations possess in themselves, especially in view of their both being upon the same woman, and alike crowned with complete success, entitle them to a place here.

The lady who was the subject of these operations was found, on her first labour, to have a deformed pelvis, the antero-posterior diameter not exceeding two inches. The consultation summoned in the case were swayed by the adverse judgment of Dr. Physick, and other distinguished surgeons, which was adverse to the Cæsarean section; and it was decided to remove the child by cephalotomy, which was accomplished by Dr. Meigs. This was in May, 1831; and in June, 1833, it became necessary for the same gentleman to repeat this operation for the removal of a second child, it being, of course, impossible to deliver per vias naturales, and the patient at the time refusing to submit to the Cæsarean section, though advised thereto.

In 1834 this lady became pregnant with her third child, and by the judicious advice of her physician, Dr. Nancrede, she consented to risk her own life in the hope of saving that of her offspring. On the 25th of March, 1835, her labour commenced; and, after the os tincæ had dilated sufficiently to admit two or three fingers, the membranes remaining entire, Professor Gibson commenced the operation, in the presence of numerous professional friends, by making an incision from below the umbilicus nearly to the pubes, the skin being lifted up and held between the fingers of an assistant, and the back of the knife being towards the abdomen. The superficial fascia, the tendons of the abdominal muscles, and the peritoneum being successively divided before cutting completely through the wall of the uterus, an unsuccessful attempt was made to rupture the membranes per vaginam, on the failure of which the remaining fibres of the uterus were divided, and the membranes cautiously opened by running Cooper's bistoury for strangulated hernia upward and downward the whole extent of the incision in the uterus, which measured six inches, the sides of the wound being held closely together, both to prevent protrusion of the intestines, and the escape of any portion of the waters into the bag of the peritoneum.

The position of the child was found to be the third breech presentation of Baudelocque. The child was then removed by the feet, which was slowly performed, and proved to be a female of large size and healthy appearance. After suitable restoratives, she breathed, and the cord being cut, she cried lustily. The placenta and membranes were then removed, and a finger passed from the cavity of the uterus through the os tincæ into the vagina. A slight protrusion of intestine occurred, but was soon restored; no fluid was permitted to enter the peritoneal sac, nor did any considerable hemorrhage occur, so that no ligature was called for. The womb began to contract, and in a few seconds the extent of the incision had visibly contracted. The edges of the peritoneum, muscles, and integuments being brought carefully together, three stout silk sutures were passed through the integuments only of the interrupted kind, an inch and a half apart, and with adhesive straps, a compress, and roller, the dressing was completed, the lower angle of the wound being left open to facilitate the discharges which might occur. The patient, being removed from the table to her bed with great care, was placed on her back, the utmost quiet enjoined, and she soon slept for several hours. No untoward symptom occurred, and on the 25th day the patient was able to sit up, the wound having healed kindly, and cicatrization being nearly complete, and soon after was restored to her wonted health. The child was named Maria Cæsareana, and continues to thrive.

On the fifth of November, 1837, Professor Gibson was called to repeat this intrepid proceeding on the same patient, she being in labour with her fourth child. The different steps in the operation were nearly the same as in the former instance; and, although her recovery was slower, yet within three months she entirely recovered, the wound throughout having firmly cicatrized. This child was found to be a male, and named Cæsar Augustus. As late as July 24th, 1841, this mother and her two children were all enjoying perfect health. The lady has not since become pregnant.

Professor Gibson has thus conferred upon himself, as well as upon American surgery, a triumph of which both may be proud, and one which Mr. Cooper has suitably noticed in his late edition. He accompanies it, however, with the announcement of Mr. Knowles's case in Birmingham, which met with success, and which was rendered necessary by a pelvic deformity originating in mollities ossium.

Professor Gibson gives the following catalogue of the conditions and circumstances under which it may become necessary to lay open the parietes of the abdomen, divide the peritoneum, and cut into the womb as in this operation: "Extraordinary diminution or deformity of the pelvis; exostosis and other tumours within its cavity; fractures of the innominata and sacrum, followed by irregularity of reunion, or profusion of callus; of dislocations of one or both thigh-bones; of wounds of the uterus; of extraordinary size of the fœtal cranium; of fœtal monstrosity; of hernia of the uterus; of preternatural presentation of the fœtus; of rupture of the uterus; of obliquity of the uterus; of large stones in the bladder; of strictures and adhesions in the vagina; of enlargement of ovaries; of extra-uterine conceptions; and other diseases, accidents, or malformations, or death of the mother." Happily, most of these emergencies rarely occur, and the propriety of the operation in some others is very questionable. So formidable a step should never be taken without grave deliberation and full consultation; and the difficulties attending it will probably deter surgeons from undertaking it, except when its necessity is decided on as called for in full view of all its dangers. In such examples, however, Dr. Gibson's success will encourage a repetition when, as in his cases, the duty of the surgeon becomes imperative.

We should never forget, however, that there have been cases in which the operation has been determined on, and yet, while the preparations were making, the child has been born per vias naturales. And, moreover, women who have suffered the Cæsarean section in a previous labour, and in one instance a repetition of it five

times, have nevertheless been delivered without it in a subsequent accouchement.

It has been suggested whether, in cases of hopeless deformity of the pelvis, the Fallopian tubes ought not to be divided in the progress of the Cæsarean section, for the purpose of preventing the risk of a repetition of this formidable operation. It would not increase the danger of the first, and would infallibly protect the patient from the hazard to life by a second resort to the section. With the consent of the patient and her husband, after explanation of its effect, there does not appear to be any moral or professional objection to adopting it. Such intelligent consent of the parties ought in all such cases to be premised, when impotence in one sex or sterility in the other is to be the result of surgery.

In the Amer. Journ. of Med. Sciences for 1835, Dr. Joseph G. Nancrede, of Philadelphia, reports the first of Dr. Gibson's operations, which. indeed, was undertaken at his instance, accompanied by an elaborate and able paper on the general subject, to which the reader is referred for details and inferences of an eminently practical character.

Dr. Valentine Mott, of New-York, has opened the abdomen for the removal of an extra-uterine fœtus, which had been borne for one year and eleven months. The case was an unfavourable one, and terminated fatally.

Dr. Hoffman, of New-York, reports a case of Cæsarean section performed by him on the person of a dwarf forty-two years of age, who was in labour with her first child, and whose pelvis was so much contracted as to render embryotomy impracticable. The case terminated favourably for the mother, but the child, which was also sadly deformed, did not long survive its delivery. The case is reported at length in the N. Y. Med. and Surg. Journ. for 1839.—Reese.]

[CANCER. Although the terms *cancer* and *carcinoma*, considered with reference to their etymology, seem decidedly to possess little recommendation, the moderns employ them with a far more precise and settled meaning than the ancients, unenlightened as they were by pathological anatomy. Still our knowledge of cancer is not even now sufficiently advanced to enable us to answer conclusively various questions respecting it. (See *Bégin* in *Dict. de Méd. et de Chir. Pratiques*, t. iv., p. 425.)

Formerly, a vast number of morbid alterations of structure, entirely different from one another, were confounded together under the name of cancer. The French ascribe to Laennec the merit of having first demcnstrated the elementary texture of true cancer, and thus freed the subject from a great deal of confusion. I believe, however, that Home, Baillie, Hey, and Abernethy had all promulgated their observations on cancer when Laennec published. According to the latter distinguished pathologist, the human body is liable to two classes of accidental productions or new formations: to the first belong certain abnormal textures, to which some of the natural tissues are more or less analogous; to the second appertain other abnormal textures, which have nothing analogous to them in any of the primitive tissues of the body. Among the productions of the latter kind, Laennec arranged *tubercles*, *scirrhus*, the *encephaloid*, *cerebriform*, or (as we more frequently call it) the *medullary tumour*, and *melanosis*. Notwithstanding all or several of these abnormal elementary modifications of disease may yet exist in tumours, vaguely called cancerous, yet, as M. Bégin well observes, and M. Laennec admits it himself, it is particularly to *scirrhous* and *cerebriform*, or *medullary* formations, that the term cancer is applied. In this article I shall exclude from consideration *tubercles*, which British pathologists never regard as cancerous, but generally as a form of scrofulous disease. Neither shall I enter, at present, into the subject of *melanosis*, which, though sometimes regarded as a species of cancer, as, for instance, by M. Alibert, who terms it *cancer mélane* (see *Nosologie Nat.*, t. i., 1817, 4to), will admit very advantageously of separate consideration. (See *Melanosis*.) According to Professor Carswell, carcinoma does not admit of a precise definition, but it may be said to consist in the formation or deposition of a peculiar substance, which presents great variety of consistence, form, and colour; frequently assumes a definite arrangement, and possesses a vascular organization of its own; gives rise to the gradual destruction or transformation of the tissues in which it is situated; affects simultaneously or successively a greater or lesser number of organs, and has a remarkable reproductive tendency. Both *scirrhous* and *medullary* cancer have long been looked upon as *malignant diseases*, though not with that discrimination and precision of meaning which the valuable remarks of Mr. Travers are likely to establish. This gentleman considers carcinoma as a genus of the order "malignant diseases," and agrees with Laennec, Carswell, and other eminent modern pathologists in enumeratmg two species of it, the *scirrhous* and the *medullary*. It is to incurableness from causes not local, and, consequently, the diposition to appear in more than one part at the same time, or to reappear when the first affected part has been freely removed, that Mr. Travers applies the term malignity. But if, from any local cause, a sore will not heal, or becomes gangrenous; if, by the extension of the ulcerative process, bloodvessels are opened, and fatal hemorrhage ensues; if, by the profuseness of a secretion, the patient dies exhausted; if, by the incessant irritation of the nervous system, or the morbid actions set up in vital organs under a protracted symptomatic fever, life is extinguished, the circumstances of the disease, viewed with reference to the above definition of malignity, would not imply that its nature was malignant. (See *Med. Chir. Trans.*, vol. xv., p. 198.)

Dr. Carswell founds the essential character of heterologous formations, of which scirrhous and medullary cancer are examples, on the presence of a substance which does not enter into the healthy composition of the body; and under the generic term of *carcinoma* he comprehends *scirrhous* (*scirrhoma*) and medullary cancer (*cephaloma*), with their varieties. His reasons for arranging these diseases together are the following: 1. They often present, in the early period of their formation, certain characters common to all of them, however much they may differ from each other in the subsequent periods. 2. They all terminate in the gradual destruction or transformation of the tissues which they affect. 3. They have all a tendency to affect several organs in the same individual. 4. They all possess, though in various degrees, the same reproductive character. (See *Carswell's Illustrations of the Elem. Forms of Disease*, *fasc.* 2.)

But, though the varieties of *scirrhoma* and *cephaloma*, as they are named by Dr. Carswell, resemble one another in the foregoing respects,

they present differences which this pathologist refers to two states of the heterologous deposite, to which they owe their origin. In *scirrhoma*, the deposite has little or no tendency to become organized. Its form and arrangement appear to be determined chiefly by external circumstances, and its production and increase are entirely dependant upon the nutritive function of the organ in which it is contained. In *cephaloma* the deposite has a greater or lesser tendency to become organized; and, "although it may at first assume a determinate form and arrangement in consequence of external circumstances, it possesses in itself properties, by means of which its subsequent arrangement and development are effected, independent of the nutritive function of the organ in which it is formed, except in so far as the materials of its growth may be derived from this source." (See *Carswell, Op. cit.*)

With respect to the varieties of *scirrhoma*, when the heterologous deposite is collected in numerous points in the form of a hard, gray, semitransparent substance, intersected by a dull white or pale straw-coloured fibrous or condensed cellular tissue, it is denominated *scirrhus*. When it assumes a regularly lobulated arrangement, so as to represent an appearance similar to a section of the pancreas, it forms what was called by Abernethy *pancreatic sarcoma*, but is better named by M. Bégin *pancreatic scirrhus*, the term sarcoma being strongly objected to by some pathologists, among whom I know is Sir Astley Cooper. Again, as Dr. Carswell observes, the heterologous deposite may be uniformly disseminated throughout the texture of an organ, which it converts into a solid substance, resembling raw or boiled pork, and named by the French *tissu lardace*, or *lardaceous tissue*. Lastly, when it presents the appearance of firm jelly, and is collected into masses of greater or less bulk in a multitude of cells, it is the *matière colloid* of Laennec, the cancer gélatiniforme or aréolaire of M. Cruveilhier. (See *Carswell's Illustrations of the Elem. Forms of Disease, fasc.* 2.)

M. Laennec entertained the belief, which is not at present adopted, that every heterologous deposite like those of scirrhus and cerebriform cancer, having nothing analogous to them among the primitive textures of the system, necessarily and invariably had two stages, one of *crudity*, the other of *softening*. The mistake on these points is, that the heterologous deposite does not always soften after a certain period, though it sometimes does so partially.

In the period of crudity, scirrhus is represented by Laennec as a substance sometimes perfectly white, but, in other instances, bluish or grayish, slightly transparent, and whose consistence is such that dividing it with a scalpel usually causes a grating sound, the consistence varying, however, in different examples, from that of the skin of pork nearly to that of cartilage. The scirrhous substance is ordinarily homogeneous, but divided into masses, which are again subdivided into lobules, united by a dense cellular tissue, whose arrangement, though exceedingly diversified, appeared to Laennec to exhibit a kind of regularity, and to resemble that of the cells of a honeycomb. In some cases, the fibrous tissue, intersecting the scirrhous substance, presents a reticulated arrangement; in some, an arborescent distribution; and in others, an appearance as if it radiated from a central point in every direction around. Some schirri, when laid open, are fancied to look very much like the substance of a turnip.

When a section is made of a scirrhus in its first stage, we find, according to Mr. Travers's description, "a tough, inorganizable, and pretty compact mass, of a white and yellow brown colour, smooth, and moistened by a slightly unctuous fluid; its consistence is not uniform, being hard in the centre, so as to form a nucleus. The circumference is defined by the termination of red vessels, forming a vascular boundary." On maceration, "the texture opens so as to bring into view concentric areolæ, having their interstices filled by a white granular matter, which may be picked out from the meshes. These areolæ are crossed by faint white lines at irregular intervals, in the direction of radii from a centre, visible to the naked eye, and very conspicuous under a magnifier, giving the section some analogy to that of a lemon. In the second stage, when inflammatory action commences, and is announced by shoots of pain, the relative firmness of the centre and circumference of the tubercle becomes reversed, the centre being pulpy or broken, while the circumference retains its firmness. The surrounding parts are now found to have lost their natural elasticity by condensation of texture, and partake of the firmness and weight of the schirrus, giving considerable apparent increase of volume to the tumour, which is now less defined at its margin, and, in fact, of a compound character." One particular opinion entertained by Mr. Travers is, that the dense opaque white lines, which, traversing the tumour in the direction of radii, and diminish in density as they proceed outward, are not the production of the disease, but the septa, which divide and support the lobules of which the gland is composed, in an opaque and thickened state. (See *Med. Chir. Trans.*, vol. xv., p. 208.) The correctness of this view seems rendered doubtful by the fact that the radiating white lines are met with wherever the scirrhous formation is met with, whether in a gland or not, and sometimes shoot into the surrounding textures beyond the limits of the part originally attacked.

Notwithstanding the essential difference between scirrhoma and cephaloma seems to Dr. Carswell to consist in the former having little or no tendency, the latter a greater or lesser tendency, to become organized, it is sometimes impossible to draw a distinct line of separation between them; for the heterologous deposite, when first formed, and, indeed, frequently for a considerable time after its formation, does not furnish any signs which show that it will or will not become organized. 1. The heterologous substance may exist in the form of scirrhus, pancreatic sarcoma, or the lardaceous tissue, without presenting any trace of organization; the textures which it invades being gradually destroyed by its presence, and both ultimately converted into a soft, granular, pulpy, or liquid mass, of the colour or consistence of cream or milk. 2. The heterologous deposite may exist under the same forms, but change into mammary or medullary sarcoma, becoming more or less soft and vascular, and frequently terminating in hemorrhage by the rupture of its vessels, or in the state commonly, but improperly, termed fungus hæmatodes. According to Dr. Carswell, numerous examples might be given of scirrhus, medullary sarcoma, and fungus hæmatodes, originating in the same morbid state, and passing successively from the one into the other in the order here spe-

cified. Indeed, all the varieties, both of scirrhoma and cephaloma, are frequently met with, not only in different organs of the same individual, but even in a single organ. (See *Carswell's Illustrations of the Elem. Forms of Disease, fasc.* 2.) A testis which I lately removed in the North London Hospital exhibited, in some places, fine specimens of mammary sarcoma, while in others its consistence was cerebriform or medullary. Sir Astley Cooper once mentioned to me a case in which he removed a diseased breast, the substance of which corresponded to scirrhus; a return of disease took place, and the tumour was then of the medullary kind. A true scirrhous texture of an unmixed form is rare in young persons. The examples in which it presents itself, in combination with medullary cancer, are principally noticed in individuals who have passed the middle period of life. Several of the varieties of both species of carcinoma appear to Dr. Carswell to differ materially from one another with regard to the comparative rapidity of their development, as well as their reproductive tendency: a fact of considerable practical importance. In both these respects, the pancreatic differs from the lardaceous, the lardaceous from the mammary, and the mammary from the medullary cancer: the first often remaining stationary for months or years; the last frequently acquiring its maximum of bulk in a few weeks, and, when removed, being sometimes reproduced with a degree of rapidity which is never observed in any of the other varieties. Generally, the more the varieties of scirrhous and medullary cancer partake of the characters of cellular, cellulo-fibrous, and fibrous tissues, *cæteris paribus*, the less rapid are they in their growth, and the less is their tendency to be reproduced. (See *Carswell's Illustrations*, &c., *fasc.* 2.)

If the disease be examined at the earliest period of its formation, while the heterologus substance has not effaced the particular texture of the part in which it is contained, the researches of Dr. Carswell prove that the morbid substance becomes manifest to our senses, either as a production of nutrition or of secretion. "In the former case (says he), it is deposited in the same manner as the nutritive element of the blood, enters into the molecular structure, and assumes the form and arrangement of the tissue or organ into which it is thus introduced. In the latter, it makes its appearance on a free surface, after the manner of natural secretions, as on serous surfaces in general."

Another interesting fact in relation to cancer is, that the heterologous substance is sometimes found within the vessels. According to M. Andral, solid fibrine in the bloodvessels sometimes constitutes in organs whitish masses, similar to cancerous tumours. In the body of a middle-aged man he found one of the lungs full of masses of this description. The middle ramifications of the pulmonary artery were gorged with solid matter, of a dirty white colour, reddish at some points, and at others liquid, and like grayish bouillie. On being attentively examined, it seemed to M. Andral to be nothing more than solid blood, reduced to elementary fibrine, with a little of the colouring matter at some points, and here and there in a state of fluidity. M. Andral traced a similar matter in the smallest vessels, as far as he was able to follow them, and he was convinced that the whitish masses with which the lung was studded, instead of being a degeneration of the organ or an accidental production in it, really consisted of small vessels filled with solid fibrine, more or less destitute of colouring matter. M. Andral likewise ascertained that cancerous masses are sometimes met with in the ramifications of the vena portæ. He noticed the same thing in the kidney: a fibrinous concretion, of a dirty white colour, was found occupying the renal vein, to the interior of which it was adherent; and it extended into the ramifications of the vessel, so that it could be traced into the smallest branches, and into parts of the kidney where, previously to the dissection, only white or pale red masses had been seen, which Laennec would have termed the encephaloid (medullary) matter in a state of crudity. M. Velpeau, who had observed similar facts, was led to infer that cancer may be primarily developed in the blood. But, instead of adopting this conclusion, M. Bégin prefers the view entertained by M. Andral, in which a certain change of the fibrine of the blood is conceived to have an important share in the formation of some cancerous productions. (See *Dict. de Méd. et de Chir. Pratique*, t. iv., p. 42.) As Professor Carswell remarks, the presence of the heterologous substance, which constitutes the several varieties of both species of carcinoma in the blood, is a circumstance of great importance; and, unless it be clearly demonstrated to arise in consequence of a modification of the blood itself, we should find it impossible to explain many of the phenomena which it presents, more especially those which accompany its formation in the molecular structure of organs and on the free surface of membranes. The following facts are regarded by Dr. Carswell as furnishing strong evidence that the formation of this substance takes place in the blood, whether it be found in this fluid alone, or in other parts of the body at the same time: The presence of this substance, 1. In the vessels which ramify in carcinomatous tumours, or in their immediate vicinity. 2. In the vessels of a portion or of the whole of an organ, to the former of which this substance is exclusively confined, and can be traced from the trunks into the branches and capillaries. 3. In vessels having no direct communication with an organ affected with the same disease; as, for example, when it is confined to a small extent of the vena portæ; and, lastly, in blood which has been effused into the cellular tissue, and on the surface of organs.

Dr. Carswell farther observes, that the divisions of the vascular system, in which the carcinomatous substance has been observed, are the venous and capillary; and that in large veins, such as the vena portæ and its branches, the emulgent vein, &c., it may present the lardaceous, mammary, medullary, or hæmatoid characters, all in the same venous trunk.

The formation of these varieties of carcinoma in the blood is a curious and particularly interesting fact, more especially as bearing upon the long-disputed question whether cancer is a local or a constitutional disease. Dr. Carswell believes that when the disease takes place in the intimate structure or on the free surface of organs, its material element is separated from the blood, and deposited under a variety of circumstances which modify its form, bulk, colour, and consistence. He cannot, therefore, imitate some pathologists, who regard the seat of the two principal varieties of carcinoma as limited to any one tissue, or who refer its origin to any modification of structure or special organization; and, with respect to the cystic origin of carci-

noma, as suggested by Dr. Hodgkin (see *Med. Chir. Trans.*, vol. xv., p. 292), he remarks, that the presence of cysts in the liver, walls of the stomach, lungs, kidneys, brain, lymphatic glands, spleen, and blood, is not to be detected at any period of the development of carcinoma, and, therefore, when they do occur in other organs, as the ovaries, testes, mammæ, &c., they must be regarded as a mere coincidence, or as a consequence of the disease, and not as a cause or necessary condition of it. (See *Carswell's Illustrations of the Elem. Forms of Disease, fasc.* 2.) The latter conclusion, I believe, has long been the prevailing one. We find it adopted by Home, Abernethy, and Travers. The latter remarks: "Within the wall of the tubercle, one or more cysts, containing a dark yellow or coffee-brown fluid, are sometimes met with, but are often not present." (See *Med. Chir. Trans.*, vol. xv., p. 209.)

Cruveilhier regards all organic transformations and degenerations as exclusively the result of the deposition of morbid products in the cellular element of organs, and he believes that their *tissus propres* are incapable of undergoing any organic lesion except hypertrophy and atrophy. But this view has been proved by Dr. Carswell to be incorrect, who shows that in the liver and stomach carcinoma can be distinctly seen to form in the molecular structure or proper tissue.

The form assumed by the carcinomatous matter seems to Dr. Carswell to be determined, in a great measure, by external circumstances. The globular shape mostly occurs in organs possessing uniform density, and in parts submitted on all sides to equal pressure. On natural and accidental serous surfaces, although the deposite may be at first globular, it frequently becomes pyriform, either on account of the mode of its attachment, or of less resistance being made to its growth in one direction than another. It assumes a fungiform shape when placed in circumstances facilitating its lateral or retarding its anterior development, as when it meets with a dense, unyielding substance during its progress, or, having pierced the skin, is subjected to pressure. When accumulated in separate portions of the cellular tissue into rounded masses, grouped together, and included within a common capsule, it generally presents a lobulated appearance, and, in the submucous tissue in particular, it frequently exhibits the cauliflower or mulberry appearance. (See *Carswell's Illustrations*, &c.)

This eminent pathologist next notices the *stratiform* arrangement of carcinomatous matter, as principally met with in the subserous cellular tissue, and frequently in the form of thin circular patches, varying from the breadth of a pin's head to an inch or more. The *ramiform* arrangement and modifications of it seem to him to depend upon the carcinomatous matter being contained in the veins, lymphatics, or lacteals.

With respect to *bulk*, Dr. Carswell explains that the quantity of carcinomatous matter deposited in the molecular structure, or on the free surface of organs, is extremely various, but perhaps never so great in the former as in the latter. In the liver it may vary from the size of a pin's head to that of an orange. In more yielding organs, as the lungs, testes, and even the mammæ, it may equal in bulk the head of an infant or of an adult, as exemplified in a cast preserved at University College, London; and, in the intermuscular and subcutaneous cellular tissue, its bulk is sometimes still more considerable.

Dr. Carswell very properly draws the attention of his reader to the influence of pressure in promoting or retarding the development of carcinomatous tumours. While their progress outward is resisted by an unyielding fibrous membrane, they often remain for a considerable time nearly stationary; but, directly this obstacle is removed, they acquire a rapid increase of bulk, and, as soon as the skin ulcerates, they often protrude in the shape of enormous fungi.

The carcinomatous swellings which attain a very considerable size are not those of a scirrhous, but of a medullary texture. In fact, as Dr. Carswell observes, the latter possess within themselves the power of increasing to an almost unlimited extent. It is to the vascular organization of such tumours that the rapidity of their growth, and their frequently great bulk, are to be attributed. A boy came to the North London Hospital with a medullary tumour, about the size of an orange, situated over the lower costa of the scapula: in ten days it occupied the whole of the axilla, reaching partly over its anterior margin, as well as very deeply into it.

I have already alluded to Laennec's doctrine that the consistence of cancer varies, and that it is greater in the early than the late stage. The term *scirrhus*, implying induration, is commonly employed to express the early, or occult stage of cancer, while a softer condition of the part or tumour is frequently conceived to indicate a more advanced period of the disease. But, as Dr. Carswell remarks, the degree of consistence of carcinomatous formations is not an invariable character of a particular stage of the development; for, when first perceptible, they may be as hard as cartilage, soft as brain, or fluid as cream; or they may become soft or fluid, after having remained for a certain time in a state of hardness.

The variety in the consistence of carcinomatous formations is ascribed by Dr. Carswell to the following circumstances: 1. The nature of the organ in which the carcinomatous deposite is contained. 2. The elementary composition of the deposite. 3. The subsequent changes, occurring either in the deposite itself, or the tissues with which it is in contact.

According to the analysis of scirrhous and medullary deposites, published by Lobstein (*Traité de Anat. Pathol.*), seventy-two grains of scirrhous breast contained:

Albumen	2 grs
Gelatine	20
Fibrine	20
Fluid fatty matter	10
Water	20
	72

Seventy grains of scirrhous uterus contained

Gelatine	15 grs.
Fibrine	10
Fatty matter	10
Water	35
	70

In the early stage of medullary cancer, the tumour contained a greater quantity of gelatine than albumen; and in the more advanced stage, when the carcinomatous matter was of the consistence of soft brain, the albumen was much more abundant than the gelatine. This statement is worthy of attention, now that medullary tumours are frequently termed *albuminous*.

According to the important researches of Pro

fessor Carswell, when we examine anatomically a mass of carcinomatous matter contained in a large vein, or situated on the surface of a serous membrane, in loose cellular tissue, or on the surface of a sore or cicatrix, we find it composed of the following elements in various proportions, viz., carcinomatous matter, cellular, fibrous, and serous tissues, and bloodvessels. The *carcinomatous matter* almost always forms by far the greater bulk of the disease. If its consistence be considerable, it presents a uniform granular or radiated arrangement; if soft, a lobulated one. The *cellular tissue* is often in small quantity, and so fine as not to be perceptible till the carcinomatous matter has been separated from it by pressure or maceration. The carcinomatous matter is enclosed in it, and separated by it into granules, lobules, &c. These it intersects in various directions, and it serves to conduct the vessels which administer to the nutrition and growth of the disease. The *fibrous tissue* is less frequently an element of carcinoma on the surfaces of organs; but the serous is often present, either rendering the carcinomatous matter encysted, or forming cysts in it of various sizes, filled with gelatinous, albuminous, or other fluid. When carcinomatous matter is deposited in the molecular structure of organs, the quantity of cellular and fibrous tissues intersecting it in various directions is sometimes very considerable. (See *Carswell's Illustrations of the Elementary Forms of Disease*, p. 3.)

In true scirrhus the traces of vascularity are very faint, but in medullary cancer the adventitious membranes possess a high degree of vascularity. The vessels ramifying in them are not only numerous, but large. By some they have been considered principally arterial; by others, venous. Dr. Hodgkin is not able to decide to which class of vessels they are most nearly allied. These newly-formed vessels, though large and numerous, are extremely weak and tender, and derive little or no support from the structure by which they are surrounded. Hence they are liable to give way at numerous points, whence proceed those frequent and extensive hemorrhages which have led to the disease, being sometimes named fungus hæmatodes. (See *Hodgkin* in *Med. Chir. Trans.*, vol. xv., p. 334.) According to Dr. Carswell, the vessels of cephaloma, or medullary cancer, vary in diameter from the breadth of a hair to that of a line, and present that peculiarity of distribution always more or less conspicuous in newly-formed vessels, namely, the ramifications of which they are composed communicate with a common trunk at its opposite extremities, in the same manner as the hepatic and abdominal divisions of the vena portæ do with the trunk of this vessel. They are frequently varicous, and seem to Dr. Carswell to partake more of the venous than the arterial character. He describes them as formed apart from the vascular system of the surrounding tissues, and constituting the *proper circulation* of cephaloma. "The communication which exists between these vessels and those of the organ in which the cephalomatous substance is contained is frequently very imperfect, a circumstance which, together with the delicacy of their structure, renders them extremely liable to congestion and rupture. The most minute divisions of these vessels terminate by penicillated extremities in the carcinomatous matter, where they communicate with veins and arteries belonging to the affected organ. The latter vessels, which may be said to form the *collateral circulation* of cephaloma, are seldom so conspicuous as the former; but there are cases in which they appear to constitute the greater part of the vascular structure of the disease." The branches seen in scirrhus or scirrhoma are only those of the vessels of neighbouring tissues, which have become enclosed within the heterologous substance. (See *Carswell's Illustrations of the Elementary Forms of Disease*, p. 3.)

Nerves have never been detected in any of the varieties of carcinoma as a *new formation;* but they are sometimes included within agglomerated tumours, or even in a single tumour that has happened to form in a situation through which they pass. (*Ib.*) Dr. Hodgkin is not aware that even a single nervous fibril has ever been discovered in the essential part of the adventitious growth. (See *Med. Chir. Trans.*, vol. xv., p. 336.) But, though the substance of medullary cancer is not supplied with nerves, the nerves may become the seat of the disease. This has often been noticed in the optic nerves. (See *Wardrop on Fungus Hæmatodes.*) M. Jules Cloquet records an instance in which a cancerous tumour was situated in the great sciatic nerve, immediately below the quadratus muscle. At some points it was very firm, at others soft, while in particular parts of it there was an obscure feel of fluctuation. Its colour was a brownish red, and its surface streaked with turgid capillary vessels. Some of the posterior filaments of the sciatic nerve passed behind the tumour, and were separated from one another on a level with it, but without any perceptible change in their organization; all the others were lost in, and confounded with the adventitious growth, which consisted of the scirrhous and cerebriform matters blended together, and presenting a marbled appearance. (See *Jules Cloquet, Pathologie Chir.*, p. 187, 4to, Paris, 1831.)

Mr. Cæsar Hawkins concurs with the observations made by Sir Astley Cooper, M. Andral, and Professor Carswell, that cancer and encephaloid tumours are allied to one another, so that the two structures may be found together, or a tumour of one kind removed from a part, may be followed in the same place by another of the opposite kind. "Even the local cancer of the scrotum may be succeeded by fungus hæmatodes; for a case of chimney-sweeper's cancer has been published by Mr. Langstaff, which was operated upon, and the patient died of fungus hæmatodes of the os innominatum, lumbar glands, and liver." (See *Lond. Med. Gaz.*, August, 1834, p. 681.) I have heard of several other cases confirming the truth of this observation; and one I saw myself, in a patient of the Bloomsbury Dispensary.

Mr. Hawkins justly observes that some parts are more liable to one form of cancer than another. Thus scirrhus is common in the breast, but fungus hæmatodes (medullary cancer) rare; while the latter disease is frequent in the testicle, and the scirrhus variety of cancer rarely seen in it. Fungus hæmatodes of a muscle, or other soft texture, runs a different course from the same disease in a bone; and cancer is modified, according as it occurs in the breast, stomach, or uterus. In the skin, particularly, a considerable difference is observed in its appearance, progress, and degree of malignancy, from cancer of other parts; and even different parts of the skin are, in some respects, differently affected. (See *Hawkins, Op. et.* vol. cit., p. 683.)

EXTERNAL CHARACTERS OF SCIRRHUS.

It was a remark made by Sir Everard Home, that when the disease originates by a small portion of the glandular structure of the breast becoming hard, it may be readily distinguished by the hard part never having been perfectly circumscribed, and giving more the feel of a knot in the gland itself than of a substance distinct from it. The disease begins at a small spot, and extends from it in all directions like rays from a centre. This is one feature distinguishing this disease from many others, which at their first attack involve a considerable portion, if not the whole of the part in which they occur. Abernethy conceived that, though a true scirrhus might be checked, it could not be made to recede by the treatment which lessens other swellings. On this point, however, he was not positive; for other surgeons had informed him that diseases which eventually proved to be cancerous had been considerably lessened by local treatment. It is to be recollected, however, that some tumours which end in cancer are not from the first of this nature; consequently, in their earlier stages, they may yield, in a certain degree, to local applications, but completely resist them after the cancerous deposite has begun. Still we have the authority of Young, Recamier, Carswell, and others, for the fact that the growth of cancer may be retarded by methodical pressure, and sometimes the disease even cured. Perhaps, therefore, to assert that a scirrhus swelling is absolutely incapable of any diminution, would not be correct. We lately had a woman in the North London Hospital whose breast I removed on account of a true scirrhus. The disease unfortunately returned in the form of hard tubercles in the skin, as well as induration of the glands of the axilla and above the clavicle. Now, in this instance, the hard masses in the skin were observed to be much smaller at some periods than others. A scirrhous tumour is sometimes surrounded by more or less inflammation of the adjacent textures; and, upon the subsidence of it, the swelling will, of course, appear lessened. Notwithstanding these circumstances, the backwardness of a scirrhous swelling to be dispersed or diminished may be set down, without risk of inaccuracy, as one of its most confirmed features.

Another character of scirrhus is to involve the contiguous textures in the same diseased action. The skin, the cellular tissue, the muscles, the periosteum, &c., all become implicated, sooner or later, if they are in the vicinity of scirrhous cancer. In this respect Abernethy recognised one difference of it from medullary cancer, which is propagated along the absorbent system, while the parts immediately in contact with the enlarged glands do not generally assume the same diseased action.

As a scirrhous tumour increases, it generally, though not constantly, becomes unequal upon its surface, so that this inequality has been considered characteristic of the disease. The circumstances influencing the shape of the carcinomatous deposite, according to Professor Carswell's views, I have already explained: they prove that the mere shape of the swelling is not a criterion of its nature.

Abernethy pointed out the error of dwelling too much on lancinating pain as a test of a scirrhous tumour: first, because it does not prevail in every case, or in every stage of cases in which it does occur; and, secondly, because it is a symptom attending other tumours which are unlike scirrhus in structure. (See *Abernethy's Surgical Works*, vol. ii., p. 69, &c.) M. Bégin agrees with Abernethy, that lancinating pain is by no means a characteristic sign of cancer; and it seems to him only to take place under circumstances where the disease is situated in an organ which is penetrated or surrounded by a greater or lesser number of nerves derived from the medulla spinalis, and suffering irritation. This happens especially in cancer of the breast, face, limbs, and neck of the womb. As for cancer (medullary?) of the liver, kidneys, spleen, and lungs, it is alleged by M. Bégin scarcely ever to produce any lancinating pain, except when the disease has extended beyond the parenchymatous structure. (See *Dict. de Méd. et de Chir. Pratiques*, t. iv., p. 434.) The fact of scirrhous tumours being often unaccompanied by such pain is now so familiarly known, that I shall merely add the evidence of Mr. Travers on this interesting point. "Not unfrequently (says he) the scirrhous tumour is perfectly inert, from the period of its formation to the close of life, undergoing very slight, if any increase, and giving, when mental apprehension is appeased, no trouble to the subject of it. A lady now under my observation has been many years so situated, enjoying uninterrupted health, though considerably above 70 years of age. The tumour is of the size of a hen's egg, and has the genuine scirrhous character. She takes sarsaparilla as a beverage; and the probability is, that what in no degree affects her health will not eventually shorten her life. (See *Med. Chir. Trans.*, vol. xv., p. 214.)

Scirrhous tumours are mostly developed slowly, without any perceptible increase in the temperature of the part, unless the textures, among which the cancerous deposite lies, happen to be the seat of inflammation. As for the heterologous substance itself, M. Bégin correctly regards it as a kind of foreign body, which may mechanically irritate the organs and textures in or among which it is placed, or more or less seriously impede their functions, so that when these are of first-rate importance in the economy, the result is inevitably fatal.

A scirrhous swelling rarely, or, I may say, never acquires the magnitude which the generality of other swellings are disposed to attain. According to Sir Astley Cooper, it usually increases from the size of a marble until it acquires two or three inches in diameter; "for it rarely happens that the true scirrhous tubercle increases to a very considerable bulk, and this circumstance is one of its criteria." (See *Lectures, &c.*, vol. ii., p. 177.) Many scirrhi are even attended with a diminution or atrophy of the part. The pressure of the heterologous deposite on the surrounding textures fully explains their occasional removal and annihilation.

By some writers unacquainted with the pathological anatomy of scirrhus, it has been asserted that tumour is not an essential character of the disease. Now this observation is only correct in a certain sense. "It is true (says Sir Charles Bell) that there is not always an increase of the dimensions of the whole breast: on the contrary, true carcinoma is often accompanied with a contraction and diminution of the general bulk. But what is true of the breast or mamma is not true of the tumour; for the proper structure of the gland either shrinks or is compressed; and sometimes the surrounding fat is diminished by absorption, so that the whole mass is less than the

natural breast, or than what the breast was before the commencement of the disease. But still the diseased part is properly a tumour; there we see an increased mass, a preternatural growth, or new matter, corresponding to the old definition *morbosum augmentum*. But farther, and in respect to the adipous membrane, the fat is not always diminished in carcinoma mammæ, but sometimes quite the contrary; and this difference in it will sometimes produce a variety in the external character, when there is none in the disease actually, or in the internal structure. Sometimes, from the diminution of fat, the irregular tuberculated structure of this disease will be apparent to the eye and to the touch, while in another patient the breast will be large, full, and smooth, only marked more than naturally with large blue veins, and having an ulcer like a hole dug in the centre of the breast." (See *Med. Chir. Trans.*, vol. xii., p. 220.)

A truly scirrhous tumour of the breast, capable of changing into open cancerous ulceration, and of a certain size, is described by Sir Edward Home as hard, heavy, and closely connected with the mammary gland, and, when moved, the whole gland moves along with it. When, indeed, all the following characters are present, no doubt can exist about the nature of the disease: an early puckering of the integuments; a dull brown, or leaden-coloured appearance of them; a knotted, uneven feel of the swelling; occasional darting pains in it; an early fixed attachment of it to the skin above, and pectoral muscle underneath; and a retraction of the nipple. According to Sir Charles Bell, it is the ligamentous bands which produce the retraction of the nipple, by extending between its ducts, and destroying its spongy texture. (See *Med. Chir. Trans.*, vol. xii., p. 233.)

Mr. Travers's description of the external characters of scirrhus is one of the best which I am acquainted with. "Hardness (says he), with increase of weight, inelasticity or toughness in some cases, knotty or craggy induration in others. Circumscription and mobility beneath the skin in its earliest stage, but not to such a degree in the subjacent bed as to allow of the fingers passing beneath the tumour and turning its edge upward. Next, *i. e.*, in the second stage, close adhesion to the tegument, and such incorporation with the glandular organ in which it is seated as to have no mobility but that of the gland itself upon the parts beneath. The adhesion of the skin either stretches, or partially retracts and puckers it, according to the smooth or unequal surface of the tumour, or to the close or loose attachment and particular conformation of the integument at the spot, as, for example, next the nipple, and at a distance from it, or beneath the mucous membrane of the pylorus or rectum, and the common integument of the body. Third stage: contraction and diminution by pressure of volume in the gland as the tumour increases. Abrupt projection of one large, coloured tubercle, sometimes of several smaller tubercles or nodules. Irreducibleness of volume and hardness by topics or medicine. Transient pains, which have been hitherto obscure and occasional, now more distinct and frequent, like the pricking of a sharp instrument, with a sense of heat or burning. Dusky or livid red colour of the skin, with resplendent tension. Excoriation or cracking of the skin at the summit or base of the tubercles, and fungous elevations, with ichorous and sanious oozing. Neither of these signs is individually diagnostic." (See *Med. Chir. Trans.*, vol xv., p. 205.) To continue the same gentleman's description, the ulcerative process at length opens the tumour, where the cracked and livid integument, previously exuding a sanious ichor, is most prominent, and the external opening is sometimes enlarged by a partial sloughing of the integument. Suppuration now takes place in the surrounding cellular membrane, and, as granulations spring up luxuriantly from the sides, the centre of the tumour gapes, and becomes a cavity more or less considerable. The granulations have a spongy or fungoid character, and are so elevated and broadly everted as to give the appearance of additional depth and breadth to the sore. "As the sloughing process enlarges and deepens the centre, the disease becomes exceedingly offensive; and although granulations continue sprouting circumferentially at the same time, they have not the power of maintaining their vitality. It is in vain that we attempt to preserve the ulcer from foulness and fetor by detergent applications; we can render it clean, but in a day or two the newly-cleansed surface ulcerates afresh instead of advancing towards cicatrization." (*Trav.* in *Med. Chir. Trans.*, vol. xv., p. 211.) He adds, that in scirrhus it is not suppuration which, as in scrofulous and other tumours, brings the disease to the surface, nor does the skin ulcerate until after the scirrhus. "Encompassed by a dense wall, the centre breaks up by ulceration, constituting the state of occult cancer. Indeed, the scirrhus is seldom removed so early as to be found with its nucleus unbroken." (P. 213.) This observation agrees with that of Laennec respecting the softening process, who only erred in representing it as invariably taking place.

On dissection, Sir Astley Cooper observes that the breast is one solid mass, like cartilage, with very little vascularity except at its edges, and internally fibrous. When the breast has acquired any magnitude, he says there is generally an opening in it, in which case it has the appearance internally of being worm-eaten and spongy. In the situation of the ulceration it is very vascular, and bloody serum is met with. The absorbent glands put on the same character as the scirrhous breast. The cellular membrane, skin, and muscles are also affected. Sometimes the diseased glands above the clavicle press upon the thoracic duct, and thus interrupt the transmission of chyle into the blood. Hence the appetite is sometimes voracious, though the patient is rapidly wasting. In the chest, on the same side as the disease, hydrothorax prevails, and the absorbents on the pleura are in a morbid state, and small white spots, like pins' heads, are visible. Traces of scirrhous disorder Sir Astley Cooper likewise represents as occasionally existing in the liver, uterus, &c.

But, on the other hand, attempts have been made by Biett, Dupuytren, and Alibert, to propagate the disease by inoculation, but always without any result in proof of the existence of a virus. The fact of the substance of cancer being often found within the bloodvessels, the same heterologous matter as is deposited out of them, sufficiently proves to my mind that the disease is constitutional, and depends upon a process by which the adventitious substance is formed in or from the blood itself.

I once attended a woman who died of cancer of the uterus, and in the same room was her mother, all the forepart of whose chest was in a

most mutilated state from the effects of sloughing, by which, at different periods, she had been freed from cancers of both her breasts. Baron Dupuytren believed that it was particularly when the cancerous mass was encysted that the whole of it was capable of being destroyed by gangrene, and the patient completely cured. (See *Journ. Hebdomad. de Med.*, t. iv., p. 38.) Many years ago, Mr. Cline had a patient in St. Thomas's Hospital, in whom the sloughing process went on to such an extent, under a linseed poultice, that the ulcer afterward healed soundly. "I have seen (says Mr. Travers) more than one case in which extensive cicatrices of ulcers existed, with much puckering and stretching of the skin of the chest, and no vestige of the breast remained. In one of these, the patient, a lady in Berkshire, resisted the pressing advice of a consultation of London surgeons to allow the extirpation of the tumour many years since. She has been in the constant habit of taking the medicine there prescribed, the extract of hemlock, almost *ad libitum*. She is still a stout, healthy-looking person, as formerly, and attributes her cure to the medicine. (See *Med. Chir. Trans.*, vol. xv., p. 213.)

Methodical compression was first recommended and practised in this country, as a means of curing cancer, by Young; and the same practice was afterward put to the test of experience in the Middlesex Hospital, from which institution the report of Sir Charles Bell tends to prove that compression, applied either to scirrhous or to ulcerated cancer, is decidedly hurtful. MM. Breschet and Ferrus also came to the same conclusion. (See *Dict. de Méd.*, 1822.) The principal advocate for it at present is M. Recamier, who attributes the failures of it in the Middlesex Hospital to its not having been applied in a suitable manner, nor modified according to the stages of the disease. M. Recamier combines likewise the administration of hemlock with a very low diet, without which, he observes, that the latter medicine produces scarcely any effect. (See *Récherches sur le Traitément du Cancer par la Compression, Simple ou Combinée*, 8vo, 2 tomes, Paris, 1829.) I lately tried Recamier's plan in a case of scirrhus in the North London Hospital, but it seemed only to accelerate the conversion of the disease into open cancer.

An escharotic, which has been of late strongly recommended for cancerous affections, is the chloride of zinc, employed in the form of paste. On this subject my friend, Mr. Crosse, of Norwich, observes, "It can, of course, only avail when the disease is still local; but the cases related by Drs. Canquoin, Ure, and Rioffrey, many of which occurred under the eye of most able surgeons, prove that this escharotic destroys the scirrhous tumour speedily, leaving an ulcerated surface, which often readily heals; and, moreover, it induces no danger from absorption, which is a recommendation not possessed by the arsenical paste." The cuticle being first removed by a blister, the phagadenic paste is applied, composed of one part of chloride of zinc and two of sulphate of lime. (See *Ure* in *Lond. Med. Gaz.*, vol. xviii., p. 287; *Conquoin, Mém. sur un Nouveau Mode de Traitément des Affections Cancéreuses*, Paris, 1835; and *Rifforey, New Treatment of Malignant Diseases and Cancer*, Lond., 1836.) This writer states that the paste not only destroys the tumour, but purifies the surrounding atmosphere. He uses the chloride of zinc, mixed with different proportions of flour, and has applied it to a tumour on the inside of the mouth, and also to the os uteri, with a good result. (See also *J. G. Crosse* in *Prov. Med. Trans.*, vol. v., p. 25.)

Dr. Ure, in some observations on lupus, recently published, communicates the following particulars respecting the chloride of zinc: "The preparation of the chloride, which I proposed and introduced into practice in this country, differs in a most important feature from that originally employed by M. Conquoin. The wheaten flour prescribed in the French formula is apt to envelop the chloride in a glutinous dough, which blunts its power, or, at any rate, tends to confine its action to the particles on the surface of the paste; but the anhydrous gypsum of my formula, while it can exercise no chemical action upon the chloride, forms a porous medium, through which the whole of the particles of the delitescent chloride may transude upon the morbid albuminous tissue, with the effect of decomposing or destroying it with certainty, to any definite depth. This preparation of mine has been adopted in several of the London Hospitals, and has been found to be unfailing in its escharotic powers." (See *Lond. Med. Gaz.*, Dec. 3, 1836.) The action of the chloride, and also of the nitrate of zinc, upon albumen, and their consequences in relation to the albumen of cancer, are discoveries to which this gentleman lays claim. (See Zinc.)—C.]

[Dr. J. C. Warren has removed three hundred carcinomatous breasts, one sixth of which have been permanently successful, no return of the disease having occurred, so far as can be ascertained, which, if truly carcinomatous, is unprecedented.

Dr. Joseph Parish, of Philadelphia, has left a valuable paper on the affections of the mammæ liable to be mistaken for cancer. (See *N. A. Med. and Surg. Journal*, vol. v., p. 269; and in the sixth volume of the same journal, p. 293, will be found another paper by Dr. P. on the diagnosis and treatment of cancer.)

The experience of Professors Gibson, Mott, M'Clellan, Eve, and, indeed, that of nearly all from whom I have heard among American surgeons, in operations for the removal of cancerous mammæ, is, that, when the disease has been preceded by scirrhus, and especially if the axillary glands have suffered, the carcinoma has returned in some of the glandular tissues, and ultimately been fatal. When, however, it has not been preceded by scirrhus, the cure by excision is often found to be permanent. Dr. Eve, of Georgia, has lately removed a cancerous lip by the method of Velpeau, extending the incision upon the interior of the lip, and relying upon effecting subsequent union between the skin and mucous membrane by the continued suture. The operation was completely successful, though the patient was of very advanced age.—Reese.]

[CANCRUM ORIS. It is a perfect specimen of phagadenic ulceration, and in its worst forms not unlike hospital gangrene, as I have seen several deplorable instances of. It also resembles the ulceration and sloughing in the mouth produced by mercury. The gangrenous inflammation of the pudenda of children is of a similar character. (See *Kinderwood* in *Med. Chir. Trans.*, vol. vii.)

The disease is rarely seen in adults, but most commonly in children from the age of eighteen months to that of six or seven years. The gums, as well as the lips and cheeks, are sometimes affected, in which circumstance the teeth are generally carious and loose. The ulceration is oc-

casionally attended with abscesses, which burst either through the cheek, lip, or just below the jaw. Exfoliations are not unfrequent, and, when the disease is neglected, extensive sloughing sometimes happens.

According to Dr. Cuming, in most instances the ulceration, commencing in the gums, extends to the lips and cheek, but sometimes it begins in the mucous membrane of the lips or cheek, and tnence extends to the gums. This disease is set down by Dr. Cuming as most frequently making its attack during the period of the first dentition, though often met with in children between three and seven years of age.

"When the disease occurs in infants on the breast, it is generally attended with a purplish and spongy appearance of the gums and roof of the mouth; and the ulceration, which lays bare the necks of the teeth, both externally and internally, is of a greenish or ash-colour, and very much disposed to bleed. The salivary discharge is increased; the tongue is white; the mouth feels hot; the bowels are for the most part confined; and the child, in general, labours under a greater or less degree of fever." (See *Dublin Hospital Reports*, vol. iv., p. 331.) Dr. Cuming has not seen this form of the disease previously to the irruption of the four superior incisors, but he has frequently seen it when the child had only six or eight teeth; and he has constantly observed that, when it occurs thus early, it is the upper gum that is first and principally attacked. This appears to Dr. Cuming the mildest and most manageable form of the disease, and he describes it as rarely attended with sloughing.

The second variety noticed by Dr. Cuming occurs in children between the ages of twenty months and seven years. The ulceration generally begins in the gums, whence it extends to the lips or cheek. Sometimes it is of an acute, sometimes of a chronic nature, and attended, accordingly, with more or less sloughing. In the very worst forms, however, though the sloughing is considerable, the ulceration is always predominant. (*Op.* et. vol. cit., p. 341.)

The third variety described by Dr. Cuming is at first confined principally to the cheek or lips. It begins with ulceration of their membrane, which is soon followed by that hard, red, shining, and circumscribed swelling, which, if the disease be not arrested, will speedily pass into gangrene. In this variety gangrene predominates over ulceration, and the constitutional disturbance resulting from it may prove fatal.

Living in a marshy situation, want of wholesome food, and inattention to cleanliness, are conducive to this disorder, which is often met with in houses where children are crowded together. One of the worst cases, however, which I have ever seen, was in a child of an opulent family in Essex. The complaint is sometimes suspected to be contagious.

The first or mildest form is well known generally to admit of being cured by purgatives, aided by some of the applications presently specified.

In the second form, Dr. Cuming, after clearing out the bowels with a brisk cathartic, confides chiefly in an alterative of mild mercurials with aperients. The local applications preferred by him are the black wash, and a dilute solution of muriatic acid in honey. When the ulcerated surface is in contact with carious or loose teeth, these should be removed. Dr. Cuming tried the liquor arsenicalis and cold salt-water bath without advantage.

In the third variety, where gangrene is predominant, the disease mostly proves fatal. Dr. Cuming has employed various local applications, such as the mineral acids, dilute and pure, the oxymel æruginis, the butter of antimony, solution of the nitrate of silver, the black wash, &c., but mostly without any good effect. I have likewise tried all these applications in vain, as well as solutions of the chloride of soda of different strength. With such external means, cinchona, sulphate of quinine, carbonate of ammonia, opium, and wine, have been prescribed, yet, for the most part, unavailingly. (See *Cuming* in *Dublin Hospital Reports*, vol. iv., p. 343, 345.)

The treatment recommended by Dease consisted in administering muriatic acid internally, using it as an application to the disease; giving the patient a nourishing diet, with jelly, wine, &c., and occasionally prescribing an emetic.

In the worst form of the disease I have found the concentrated nitric acid one of the most useful applications, especially when assisted with the internal exhibition of sulphate of quinine and dilute sulphuric acid.—C.]

[CARBUNCLE. Besides the diffuse forms of gangrene and sphacelus of the subcutaneous cellular tissue, there is likewise "a circumscribed form, which is observed in furunculus, carbuncle, or anthrax. The great accumulation of blood, and the still greater and rapid effusion of serosity, which takes place in these circumscribed acute inflammatory affections, produce a state of extreme induration of the cellular tissue, a greater or lesser portion of which, being thus as if strangulated, dies from want of nutrition, becomes separated from the living parts, and is expelled in the form of a gray or straw-coloured spongy or pulpy mass, through an opening made in the skin by a similar process, by ulceration, or a surgical operation." (See *Carswell's Illustrations of the Elementary Forms of Disease*, p. 7.)

Anthrax, or common carbuncle, resembles a boil (see Furunculus) in being attended with gangrene of the subcutaneous cellular tissue, and, if one high authority can be credited, of certain processes of that texture within the skin. (See *Dupuytren, Clin. Chir.*, vol. iv., p. 109.) It is remarkable for constituting a circumscribed dark red or livid swelling, accompanied by burning heat, stiffness, and for soreness in the part; and occurring most frequently in parts of the body where the skin is thickest, and abounds most in those processes of cellular tissue which are described by Dupuytren as extending between its areolæ. Thus the nape of the neck, the back, the spaces over the scapulæ, the sides of the chest, and the nates, are the ordinary situations of anthrax.

Anthrax differs from a boil not only in being of more considerable size, but in being usually single, and bursting by several small apertures; whereas several boils frequently form together or occur in succession, and when one of these tumours bursts, it does so by a single opening in its apex. The skin which covers the anthrax, and especially what lies over its centre, is of a deeper and more livid red colour than what is seen over a boil. The mortified cellular tissue is deeper and more extensive in anthrax than a boil, in which it forms only a central nucleus or *core*. The surface of the tumour is flatter than that of a boil, which always rises in a conical shape above the level of the skin, while its base

does not penetrate so deeply as that of a carbuncle, which is a great deal broader than the more superficial part of the tumour. It is the nature of anthrax to produce gangrene and disorganization of the subcutaneous cellular tissue, and sometimes a destruction of even the subjacent muscles and deeper textures, the mass of dead parts constituting frequently a slough of a lightish colour, portions of which, mixing with the discharge, sometimes communicate to it an appearance compared by Sir Astley Cooper to that of flour and water. Sometimes, however, the matter is bloody and sanious. Boils chiefly occur in children and young plethoric persons; the anthrax is mostly seen in subjects beyond the middle period of life, whose constitutions have been seriously impaired by intemperance or other causes.

The occurrence of anthrax on the limbs is uncommon. Mr. Hunter, however, had seen the disease so situated: I have met with examples of it on the occiput, side of the neck, in various parts of the back, and on the nates.

Anthrax, or common carbuncle, is essentially different from the malignant pustule, so frequent in some of the southern parts of Europe (see *Larrey, Mem. de Chir. Militaire*, t. i., p. 104, &c.), in not being contagious. It differs also from pestilential and malignant carbuncle (the *charbon* of French pathologists) in the same important respect. (See *Dupuytren, Clin. Chir.*, t. iv., p. 111.) This latter also regards the malignant pustule and pestilential carbuncle as essentially gangrenous diseases, whereas simple anthrax seems to him to be so merely from strangulation of the processes of cellular tissue extending into the structure of the true skin. The correctness of this statement seems to be rather doubtful, because there can be no carbuncular disease, whether benign or malignant, without a gangrenous disorganization of the cellular tissue, and the influence of constitutional causes. This is certain; but, whether constriction of the inflamed tissues, as alleged by Dupuytren, be the principal cause of gangrene, is a point which is far less clear. We find, indeed, that it is the character of carbuncular inflammations first to produce sloughing of the cellular tissue, even where this may not be covered by any dense unyielding parts, though occasionally it afterward destroys all textures down to the vertebræ or scapulæ themselves. The gangrene, I should say, is independent of the constriction and confinement of the textures affected.—C.]

[CARIES. The prominent feature both of ulceration and caries is loss of substance through absorption. But, as Mr. Mayo properly observes, "caries is something more than mere absorption. When an aneurism of the aorta presses against the sternum or the vertebræ, the bones are gradually eaten through; they are partially absorbed, but they are not carious. When, however, the face is attacked with lupus, and the ulcer, spreading in depth and breadth, reaches the bones, and they become excavated simultaneously with the soft parts in the enlarging ulcer, the osseous tissue is not only absorbed, but truly carious. In caries, absorption is preceded by a change in the bone, which (with very few and doubtful exceptions) has a well-marked inflammatory character. The same condition exists during the progress of the absorption. There is farther present an imperfect restorative action, which is shown in the more or less partial growth of unwholesome granulations from the ulcerated surface. Of these changes, the inflamed condition of the bone is the primary and most important; the absorption is secondary and accidental. Absorption may be prevented by subduing the inflammation, or may, after having begun, be arrested, and the crop of unwholesome granulations converted into a healthy restorative growth, if the case is of such a nature as to allow of the suppression of the inflammatory or specific action."

Mr. Mayo enumerates four kinds of caries: 1. *Simple;* when, in a person of sound constitution, a state of unwholesome and protracted inflammation is set up in a bone through some accidental local cause. 2. *Syphilitic;* when a disposition to a specific periosteal inflammation is produced by lues. 3. *Strumous;* when the scrofulous diathesis gives origin to caries. 4. *Malignant;* when the bones are absorbed in the spread of malignant ulcers. (See *Outlines of Human Pathology*, p. 36.)

According to Mr. Mayo, syphilitic caries begins with inflammation of the periosteum, and "does not lead to much enlargement of the bone. The bones commonly attacked are those which, lying near the surface, are obnoxious to cold: the tibia for instance, the ulna, the clavicle, the cranial bones. The swelling by which syphilitic caries first manifests itself is called a node. It is an inflammation either confined to the periosteum, or involving, at most, the cortex of the bone. The periosteum becomes thickened, and is exquisitely painful. If the integuments are divided down to the bone at this period, a thick, viscid, glairy matter, like honey, is often found in the cells of the periosteum, &c. The surface of the bone now gradually enlarges, or is thrown up in particles of porous bone, either furrowed by longitudinal grooves, or spongy and sieve-like, riddled with innumerable minute holes." The outer table of the scull, in venereal caries, generally has the appearance of being worm-eaten. Mr. Mayo adds, that while the caries is making progress, the integuments inflame, and matter forms below the skin, which afterward ulcerates. The skin, before breaking, has a livid colour, and afterward the skin around the ulcer has the same hue. The edges of the sore are commonly a little raised, its outline uneven, and the granulations irregular, and covered by a viscid, ash-coloured secretion. A probe readily passes through the soft and gritty texture of the caries. The coexistence of ulcerated fauces and squamous eruption, or other disease of the skin, generally leaves no doubt of the nature of the caries. Sometimes, however, the latter exists alone. (See *Mayo's Outline of Human Pathology*, p. 40.)

Mr. Mayo is unacquainted with any essential difference in the appearance of carious bones in some forms of scrofula, and in the parallel cases dependant upon lues. "Less pain, less periosteal inflammation, and a smaller extent of surface attacked, the absence of other symptoms, and the general physical appearance of the patient (he adds) afford a strong presumption of the scrofulous origin of the disease." (*Op. cit.*, p. 41.)

The instances of malignant caries adduced by Mr. Mayo are those from lupus and cancer (p. 48).—C.]

[CATARACT. Professor Dugas has succeeded in restoring sight to a child suffering from congenital cataract on both eyes by the operation of lacerating the lens. The child was three years of age.

Dr. M'Clellan has been very successful in the cure of cataract, and has performed extraction 72 times, chiefly for the hard variety. In capsular and lenticular cataract, he relies upon simply excising a portion of the anterior capsule with a curved needle, and avoids disturbing the vitreous humour, or even dislocating the lens. He has had extensive experience in making an artificial pupil, having repeated this operation very frequently with success.—REESE.]

[CLAVICLE. Dr. J. C. Warren, of Boston, has performed the exsection of the clavicle for osteosarcoma, but without the success which attended the operation of Dr. Mott, and its repetition recently by Mr. Travers.

Dr. M'Clellan, of Philadelphia, has successfully removed the clavicle and scapula for the same disease, and the patient has recovered. Dr. Mussey, of Cincinnati, has also successfully accomplished the removal of these bones in a case, the particulars of which possess great interest. (See *Amer. Jour. of Med. Sciences for* 1838.)

Dr. T. D. Mutter, of Philadelphia, has removed a part of the clavicle at its sternal extremity, including a portion of the sternum, for caries of these bones. The space thus left at this important point of articulation has been filled by a fibro-cartilaginous structure, so that, in eight weeks after the operation, the motions of the upper extremity were perfectly restored.—REESE.]

[CLUB FOOT. In the article Tendons, Mr. Cooper has only made a brief reference to the new operation of dividing the tendons for the cure of talipes or club foot, and for the removal of other deformities; and in the Addenda I find the following article on the subject:

[CLUB FOOT. In the article Tendons I have noticed the operation of dividing the tendon of Achilles as a means of restoring the foot to its proper position in certain examples of this deformity. A great deal has been published on the subject of machinery for club feet; but, as Dupuytren justly observes, the history of such cases was left very defective in consequence of no anatomical examination having been made of the parts affected. In the most frequent congenital distortion of the foot, termed by the ancients *varus*, the point of it is turned inward, and the dorsum downward, so that the patient walks on its outer edge, and sometimes even upon the dorsum itself. The second much less frequent variety is that called *valgus*, in which the foot is turned outward. There is also a third variety, in which the point of the foot is drawn backward, and the position of the whole foot is so reversed that the patient walks entirely upon the instep. Dupuytren looks upon a dislocation of some of the bones of the tarsus, together with a subsequent change in the arrangement of the ligaments and muscles, as the essential cause of the deformity. All the external appearances of club foot were well described by Scarpa; but, according to Dupuytren, no writers have called attention to the affection of the nutrition of the limb and its atrophy. "The deformity (says he) may be restricted to one foot, or extended to both. In the first case, if the infant be examined shortly after birth, the affected foot will usually be found rather smaller than the other, but the two limbs are of the same length. When both feet are implicated, they are, in general, equally developed. In proportion as the time from the period of birth becomes longer, the atrophy becomes more and more evident, and the cause of it is very explicable. In fact, the child, from instinct, as it were, bears upon the sound foot, on which all the weight of the body is thrown. The result is, that its nutrition is more active; while the deformed foot, remaining comparatively inactive, must, on the contrary, dwindle away.

"But this atrophy is of two kinds, which have hitherto been confounded, though they should be discriminated: 1. Atrophy, according to the diameter of the limb; 2. Atrophy according to its length. The first kind chiefly affects the muscles, and hence the slenderness and weakness of the limb; the second extends both to the muscles and the bones, but its action on the skeleton is the most serious and important; for the atrophy of diameter may always be removed by exercise of the muscles when the club foot has been rectified, while nothing can correct the shortened state of the limb." Though the shortening of the muscles and tendons is generally less in degree than that of the bones, yet it seems to Dupuytren that it should be taken into consideration: "Thus (says he) the tendon of Achilles, at the age of twenty, has lost so much of its length, that, even after the natural direction of the foot has been restored, the patient, in order to be able to bear on the ground, is obliged to wear a high-heeled shoe." Hence Dupuytren insists on the prudence of beginning the treatment of club feet very early, in consequence of the greater facility of the cure. In a very young infant, the foot may be rectified by the mere hand, and without pain; but at the age of ten or twelve years, machinery becomes necessary, and at a later period it fails, for nothing will then restore the length of the limb, nor even its shape and complete functions. (See *Dupuytren, Chir.*, t. iii., art. 6.) Occasionally a club foot undergoes a spontaneous cure, of which an instance is recorded by Dr. Holtj. (See *Repertoire d'Anat. et de Physiologie.*)

The cure of club feet by division of the tendo Achilles, in cases otherwise irremediable, is one great improvement in modern surgery. Indeed, the division of other tendons for the relief of the permanent contraction and shortening of muscles is now occasionally practised with decided success. (See TENDONS.)—C.]

[The novelty of this subject, and its importance to the profession, as well as the attention these operations have received in America, require a much fuller notice than is here given. The numerous examples in which myotomy and tenotomy have been repeated in various congenital and morbid deformities, both in Europe and in this country, have created a new speciality, which has received the name of Orthopœdic Surgery, and one which is deservedly attracting a large share of attention both from the profession and the public.

The original suggestion of cutting asunder the tendo Achilles for club foot is due to Thilenius, a German physician, and in 1784 it was successfully performed by his direction. Michaelis in 1809, and Sartorius in 1812, repeated it in Germany with the like success. The lamented Delpech performed it in France in 1816, but, though successful in the end, the cure was so long delayed, and attended with so much difficulty and danger, that his countrymen discouraged its repetition, and for the time the subject seems to have been everywhere abandoned. Indeed, when it is recollected that the frequency of this deformity in every country was notorious and its victims included some of the most distin

guished men among the European aristocracy, of whom were Prince Talleyrand, Lord Byron, and Sir Walter Scott, and that, for the removal of these deformities, no effort was made, we have the most conclusive evidence that no confidence existed in the safety or propriety of the operation. Amputation of the offending member was the only resource which our art afforded, and this was accordingly performed in numerous instances. An eminent surgeon in New-York amputated the limb of a gentleman for club foot as lately as 1834.

In the year 1831, Dr. Stromeyer, a celebrated German surgeon, revived the operation, dividing the tendo Achilles by a subcutaneous incision; and, having been successful in two cases of club foot without any untoward symptom having followed, he soon after published an account of the cases and their results. Among the earliest of his imitators were Dr. Dickson, of North Carolina, in 1835, Dr. N. R. Smith, of Baltimore, in 1836, and Dr. William Detmold, then of Hanover, but now an eminent surgeon in the city of New-York, in 1837; and the latter having been the first to publish an account of his operations in the United States, which he did in the American Journal for May, 1838, he has probably had more extensive opportunities than have fallen to any other surgeon, either in the Old or New World. Dr. Detmold has now performed more than 400 operations on club foot, and divided more than 1200 tendons on Stromeyer's plan of subcutaneous incision.

His extensive opportunities and experience have proved, 1st, that the dangers formerly supposed to be consequential upon wounds of tendons are wholly imaginary; 2d, that the union of a divided tendon takes place readily and infallibly, however far the cut ends are separated by the restoration of the heel and foot to its normal position; 3d, that a large proportion of the deformities called club foot, including congenital cases, regarded as hopeless malformation, can be cured by the division of the several tendons upon the contraction of which the deformity depends, and by means of subsequent mechanical management. In all his experience he never saw an ununited tendon follow his operations, nor has he had a single example of trismus or any other troublesome sequela.

In the last edition of the Institutes of Surgery by Professor Gibson, of the University of Pennsylvania, will be found a highly interesting and discriminating account of the nature, causes, varieties, and treatment of club foot, written for the work by a son of the author, Dr. Charles Bell Gibson, of Baltimore, a young surgeon who gives promise of early eminence in his profession. From this article it will be seen that the disease may be either congenital or accidental. The former are ascribed by him to some malposition of the feet in utero, and the latter may result from fractures, luxations, sprains, ulcers, or partial paralysis.

He enumerates five varieties of club foot, viz., 1st, *Pes equinus*, when the patient walks on the toes or the metatarso-phalangeal articulation; 2d, *Varus*, in which he stands upon the outer position of the dorsum of the foot; 3d, *Valgus*, in which the limb rests on the inside of the foot; 4th, *Phalangeal*, in which the patient stands on the dorsal face of the cuboid and cuneiform bones of the tarsus, the toes and metatarsi being turned under the heel, and the fore part of the foot beneath the axis of the limb; and, 5th, *Talus*, in which the heel being directed downward, the dorsum of the foot is applied in front of the leg.

The varieties of club foot have been thus more intelligibly defined, viz., *Talipes equinus*, abnormal extension of the foot; *Talipes calcaneus* or *talus*, abnormal flexion; *Talipes varus*, extension with adduction; *Talipes valgus*, flexion with abduction. The other varieties will be found to be but complications of these, or greater or less distortions, though belonging to one or more of these four.

Of these varieties the most common would seem to be a complication of the first and second varieties, and each of these five varieties, though easily recognised, will be found more or less deformed by the greater or less extent of the displacement, diagnostic of each. And wher they depend in whole or in part upon muscular contraction, a number of tendons other than that of the gastrocnemii will be found to be involved. Cases of double club foot are often found among congenital examples.

In regard to the treatment of club foot, Dr. Gibson, beginning with the bandages, friction, and shoe employed for the purpose by Hippocrates, traces down to the present time the multiplied surgical and empirical methods to cure these deformities by mechanical apparatus, of which, indeed, both he and his distinguished father seem disposed to speak with much favour; and they express a doubt as to the proportion of benefit derived in successful cases from the division of the tendons, when the apparatus is superadded in the subsequent management; and they seem inclined to ascribe the cure to the apparatus alone, which they regard as in most cases a competent remedial agency in the removal of these deformities. The apparatus of Dr. Heber Chase, of Philadelphia, is spoken of as having been successful in removing the deformity of club foot, in its different varieties, by mechanical means alone.

The principles upon which Dr. Chase's apparatus operates are nearly the same which have been from time immemorial regarded and practised, unhappily, however, with but little success, except in uncomplicated cases, or when applied soon after birth, in the congenital variety. For the accidental form of talipes, or when the case is in an adult, the utility of any form of curative apparatus has been more than doubtful, until the cases reported by Dr. Chase have inspired hope that such deformities may be removed by his modification of mechanical means, which, it must be confessed, possesses the merit of greater simplicity than the very complex apparatus formerly employed. His experience thus far has been highly satisfactory; and some of the cures, reported in the American Journal of Medical Sciences and other periodicals, while they reflect great credit on his science and skill, do certainly render it probable that a large proportion of these and other deformities, for which myotomy and tenotomy are coming in vogue, may be better removed by mechanical means than by the use of the knife. Still, however, it must be conceded, even by those who have arrayed themselves against the innovations of orthopœdic surgery, that there are varieties of club foot for which the division, not merely of the tendo Achilles, but of the tendons of the anterior and posterior tibial, peroneal, &c., will be found indispensable as preliminary to the successful employment of any apparatus; and, as in all cases after the opera-

tion of tenotomy, precisely similar mechanical means are demanded as when these are exclusively relied on, there need be no strife between the advocates of either method other than a laudable ambition to excel in their success by removing the deformity, and restoring the limb to comeliness and utility. No enlightened or reputable surgeon will be inhuman enough to practise the operation in any case where mechanical means hold out a rational hope of success without it; nor should any such hesitate to divide tendons or muscles, to any extent demanded, for the removal of such deformities, after the multiplied and satisfactory proofs before the profession of the safety and benefit of these operations, even in cases to which no mechanical apparatus could by possibility be adapted, or in which the attempt has been fairly and fruitlessly made.

In Europe, tenotomy has been very frequently performed in these cases by Dieffenbach, Duval, Bouvier, Roux, Liston, Whipple, Keate, and others; and in this country, since it was introduced to the profession by Dr. Detmold, it has been repeated by surgeons in almost every part of the country. Professor Mott has returned from his European tour and temporary foreign residence so impressed by what he witnessed while among transatlantic surgeons, that he has projected in New-York an orthopœdic institution, devoted to the reception and treatment of all the deformities and malformations for which this new department of surgery is adapted, and which he designs shall be a school for teaching this speciality, and widely diffusing its advantages throughout our country by clinical lectures and published reports of cases. Dr. Detmold, meanwhile, is almost daily receiving patients in the same city from various parts of the United States, by which it is ascertained that the cases of club foot are vastly more numerous than was ever imagined until this method of cure was announced. As this gentleman has devoted himself almost exclusively to this department for a number of years, and is now engaged in lecturing on the subject before the College of Physicians and Surgeons in New-York, I would refer to an elaborate paper on the subject in the N. Y. Journal of Medicine and Surgery, which is remarkable for its eminently pathological and practical character. It may be found in the number of that quarterly for January, 1840.

From Dr. Detmold's valuable publications on this subject, I must content myself with a brief analytical summary of his theory and practice. He ascribes club foot and kindred deformities invariably to the same cause, a disturbance of the equilibrium between antagonist muscles, and he examines the adverse opinions of other surgeons on this topic at length. At the date of the publication, 1840, he had been consulted in 167 cases, of whom 98 were males and 69 females. In 93 both feet were affected, in 41 only the right foot, and in 33 only the left foot. Of the 167 cases, 125 were congenital. Of these, 114 were otherwise well formed; 11 had some other congenital defect, apparently independent of club foot; in two the whole extremity, femur and tibia, were unnaturally short; in one only half the length of the other sound extremity; one had a harelip; seven squinted; one had the toes of the club foot grown together; and one had an additional thumb, that is, two thumbs on the hand corresponding with the club foot. To these and similar statistical information, collected with great discrimination by Dr. Detmold, he has diligently inquired into the proportion of hereditary cases, which in almost every instance is on the father's side, perhaps for the reason that club foot females seldom marry; and Dr. Bedford reports a single example having occurred in his practice of a club-footed mother whose infant had the maternal deformity.

Of the 167 patients, 93 being double club-footed, furnish for the statistical inquiries 260 club feet; and of these 230 were of the species called talipes varus, which is vastly the most frequent form of the distortion. Only 11 were of the species called talipes valgus; 17 were of the form named talipes equinus; and but one of the species termed talipes calcaneus, and it existed in both feet, which must be the rarest variety. Dr. Detmold suggests for this last variety the name talipes equestris, for the reason that it resembles the position of the foot in the stirrup in the act of riding.

In respect to the treatment, we have here a critical and, no doubt, accurate investigation into the cases which may be cured by mechanical means alone, and those in which tenotomy is either necessary or advantageous. Dr. Detmold is far from advocating the indiscriminate division of tendons by the knife in every case of club foot, and still less does he approve of the practice, sometimes resorted to unnecessarily, of cutting a number of tendons. He insists that in a great majority of cases the division of the tendo Achilles is the only cutting which is demanded, especially in young subjects, though he admits that sometimes, in older subjects, the cure may be facilitated by dividing, in addition, the tibialis anticus and posticus, the flexor longus, and sometimes the extensor pollicis; and in pes equinus, the peroneal, and that, in deformities of long standing, time may possibly be gained by cutting the ligamentum plantare. Still, in nearly all cases, it is better only to divide the tendo Achilles, and then attempt the cure by extension, at least postponing any farther division of tendons until, in the progress of the treatment, it becomes absolutely imperative.

Our space will not permit the introduction of the exposition given of the modus operandi of tenotomy, or the reasonings by which it is sustained. Nor can we enter upon the details concerning the instruments, or the manner of using them, either for dividing the tendons, or for supporting and extending the limb, in the subsequent mechanical treatment. It must suffice to remark that Dr. Detmold is opposed to the *immediate* extension of the foot by any apparatus, but prefers waiting two or three days after the operation. The apparatus of Stromeyer has been improved by Dr. Detmold, and he greatly prefers it to the mould of plaster of Paris over the deformed foot recommended by Guerin; he also employs the shoe of Scarpa.

Dr. Detmold has divided the musculus pectineus in a case of contraction of the hip-joint, which was materially relieved, but he regards distortions of this joint unfavourable for the success of tenotomy. So, also, he doubts whether, in contractions of the upper extremity, we can ever be so successful as in the knee and foot, though he has relieved contractions of the elbow by dividing the biceps, and those of the wrist and fingers by cutting the flexors. The difficulty in these cases arises mainly from the impracticability of subsequently availing ourselves of mechanical means of support and extension, while in contractions of the knee and ankle-joint my-

otomy will seldom fail, it being so easy to adapt the apparatus to the lower extremity.

Dr. Detmold speaks favourably of the division of the sterno-cleido mastoideus for wry neck, but expresses himself doubtfully of M. Guerin's operations on the muscles of the back for lateral curvatures of the spine. The success which has attended this operation, however, in the hands of Guerin, since this paper was written, would seem to promise much from it in future. It is worthy of remark, however, that Dr. Detmold suggests the division of the muscles of the eye in strabismus, and avows his conviction that, like club foot, it depends on spasmodic muscular action, and he only hesitates in recommending the division of the muscles of the eye from a doubt whether the slight inconvenience would justify such an operation. At the time this paper was written, Stromeyer had, in like manner, made the suggestion, but the operation had not then been performed.

Dr. Detmold's paper concludes with a detailed narrative of thirteen cases, with their treatment, of which we have only room for an extract from the summary, by which we learn that of the 230 cases, the tendo Achilles alone was divided in 163, and in seventeen, this, with other tendons, and the aponeurosis plantaris. In three cases the operation was repeated on the tendo Achilles. All the eleven cases of valgus, and the only two of calcaneus, together with forty-five of varus, were treated by mechanical means alone, without tenotomy.

For other muscular contractions, Dr. Detmold has divided 1 sterno-cleido mastoideus, 1 biceps brachii, 1 flexor carpi radialis, 1 flexor carpi ulnaris, 1 palmaris longus, 1 flexor digitorum manus sublimis, 4 flexor tendons of separate fingers, 1 pectineus, 6 biceps femoris, 7 semimembranosus and semitendinosus, 5 extensor tendons of separate toes, 3 flexor tendons of separate toes, besides a number of times different portions of fasciæ and aponeuroses. In all these instances the division was effected subcutaneously, and the external wound healed by the first intention.

Dr. Mutter, of Philadelphia, has also acquired great and merited reputation in orthopœdic surgery, and his opportunities have been extensive. He has already treated more than 200 cases of club foot, either with or without tenotomy, 12 cases of wry neck, 4 cases of contracted elbow, 15 of contracted fingers, 32 of contracted knees, 3 of rigid masseters, and 80 of strabismus, and has had extraordinary success.

The extent to which tenotomy and myotomy has been practised, especially in Paris, may be estimated by an example recently published by M. Jules Guerin, of Paris, in which he made a subcutaneous section of forty-two muscles, tendons, and ligaments on the same person and at one time, for the cure of a general articular deformity; and yet, in this and similar extraordinary instances, no untoward results have followed.

M. Guerin, who is the celebrated editor of the Gazette Medicale, has also applied the principle of division of tendons to remove lateral curvatures of the spine, and many cases, both in private practice and at his orthopœdic institution near the Bois Bologne, attest the success which has crowned his efforts, conjoined as they are with pure science and consummate mechanical skill.

In Dunglison's Amer. Med. Intelligencer for May 1st, 1840, there is an article by A. G. Walter, M.D., of Pittsburg, by which it appears that Dr. W. has greatly improved the condition of a patient suffering under extensive deformities of the lower limbs, by dividing the tendons and muscles of the hip, the knee, and the ankle. He first divided the attachment of the adductor longus and gracilis muscles, with the fascia lata on each side, by introducing the knife about an inch below Poupart's ligament, and thus abducted the femur, which was before impossible; next he cut the tendons of the sartorius, gracilis, semi membranosus and semitendinosus on each limb, and thus was enabled to give extension to the knee, which had been permanently flexed; and, lastly, he divided the tendo Achilles and peroneus of each foot, for the removal of that variety of club foot called valgus. He prefers, for the division of the peronei muscles, to go below the malleoli externi. All these tendons were divided subcutaneously, making five incisions through the skin for dividing the muscles and tendons on each extremity. Subsequently he adopted mechanical treatment, and, at the time of the report, his stature had increased six inches, and with the aid of crutches he could walk very well, and there seemed every prospect of complete success attending the operation, though the case was an unfavourable one, owing to the long continuance of constitutional disease from childhood, the spasms and other nervous affections which complicated it, and the number of years in which locomotion of the limbs had been out of the question. The complete removal of the deformity of the several joints, and the improvement of the patient by allowing the exercise necessary to his restoration, of themselves entitle the operator to great merit, and constitute very creditable success, even if no farther improvement should be attained.

Dr. Alfred C. Post, of New-York, has treated with success a considerable number of cases of club foot and other analogous de ormities. In one case of complicated deformity, he divided the tendo Achilles, the plantar fascia, the tendons of the tibialis anticus and posticus, and of the flexor longus pollicis pedis, the ten extensor tendons of the toes, the peroneus longus, the semimembranosus and semitendinosus, the gracilis, the adductor longus, and the tensor vaginæ femoris of the right side; also the tensor vaginæ femoris and adductor longus of the left side. Dr. Post has introduced some ingenious and useful modifications of instruments used in the treatment of these deformities.

An invaluable treatise on this subject has been published by Dr. Little, of London, on the nature of club foot and analogous distortions, including the treatment both with and without surgical operation, and to this work the young surgeon may refer for detailed practical information, illustrated by numerous cases. Dr. Little was himself a victim of congenital talipes, and had long projected the division of tendons on his own foot, and had only been deterred by the sad results of Delpech's case, and the adverse opinion of his professional brethren. Having learned the success of Stromeyer, he proceeded to Hanover, and became the patient of that eminent surgeon in 1835, by whom his own deformity has been cured. Since then, during his stay on the Continent, Dr. Little has been repeating the operation on others, and on his return home he had the honour of introducing the Stromeyerian method into the British metropolis.

M. Bouvier, of Paris, and Mr. Whipple, of

London, had anticipated Dr. Little, according to the plan of the former gentleman, Mr. Whipple having thus divided the tendo Achilles as early as May, 1836. But Dr. Little was the first British practitioner who practised the Stromeyerian method of cure, his first case in London being performed February 20th, 1837.

It seems, however, that Dr. Thomas Inglis, of Glasgow, as early as 1822, guided only by his sensations and his vehement desire to relieve himself from the deformity, he being afflicted with congenital talipes equinus, boldly divided the tendo Achilles of his right leg. Dr. Inglis was at the time a young man, and had not yet commenced his medical studies; of course, he rudely cut from without inward, through the skin, fascia, and tendons, having no knowledge of the subject, but desperately determined to remove his lameness, even at the risk of his life. The hemorrhage so alarmed the family that he was placed under surgical treatment, and the foot bandaged in a state of extension, the edges of the divided tendon kept closely in contact, and he being prohibited from walking until the union was complete. No untoward circumstance delayed adhesion, but the deformity was, of course, unchanged. Thus he remained until 1837, when he went to London, and placed himself under the treatment of Dr. Little, by whom the same operation was repeated on the 11th of August; and in three days, the puncture having cicatrized, Stromeyer's foot-board was applied for extension, and in a few days the foot was as much bent at the ankle-joint as that of the opposite limb, and Dr. Inglis is at length perfectly cured of his deformity.

So frequently have patients suffering from club foot ascribed their deformity "to the cord behind the heel," that nothing but the imaginary danger of wounded tendons could have prevented the surgical expedient now so successfully adopted. Indeed, the earnest remonstrance of surgeons against cutting the tendo Achilles has often been necessary to prevent others besides Dr. Inglis from making the experiment on themselves, so conscious have they been that their deformity depended on this "cord behind the heel."

Among the varieties of cases related by Dr. Little as having been treated by him, will be found congenital and non-congenital examples, of one foot or of both feet, and existing either as T. equinus, T. varus, T. valgus, or T. calcaneus, with and without the complication of these varieties. In numerous examples of congenital club foot, we have coexisting in the same patient the analogous deformity of club hand, and which is found to depend on similar muscular contractions, the flexors and pronators of the hand being affected like the extensors and adductors of the foot. So, also, in still other congenital cases of club foot and club hand; congenital squinting and congenital stammering are found to be simultaneously present, and which may be ascribed in such examples to the increase of the voluntary, or the decrease of the involuntary motor powers of the orbital and laryngeal muscles. And it is a remarkable fact, that even some cases of non-congenital club foot are complicated with strabismus.

In respect to the causes of club foot, a variety of conflicting opinions still divide the profession; the most probable of which is, that it depends in all cases upon spasmodic muscular contraction, and may therefore originate from any cause capable of producing this morbid condition, whether applied before or after birth. This pathology of these deformities will explain the fact that it so often occurs after birth and at various ages, while these non-congenital examples are found to possess the same inflexible and essential peculiarities as the congenital affection, advancing often to the same grade of deformity, and remediable by the same means. The better knowledge we now possess of the morbid anatomy of these deformities, and our experience as to the curability both of the congenital and non-congenital varieties, prepare us to reject many opinions as to their causation, which have been adopted for want of these guides by those who have heretofore investigated the subject; for nothing can now be more certain than that the cases which are known to have originated during fœtal life, and those which have occurred long after birth, are identical in their nature, and are dependant on some common cause.

In regard to congenital cases, there is nothing unphilosophical in admitting the ancient opinion that a severe fright to the mother during pregnancy may be one of the sources of club foot; for a violent mental impression made upon the maternal circulation may so disturb that of the fœtus as to affect the brain and spinal chord of the infant, and result in spasmodic contraction of various muscles, leading to different kinds of deformities. This theory, which ascribes the deformity to some cause resident within the organization of the fœtus, is incomparably more plausible than that which attributes it to mechanical pressure, or the entanglement of the limbs in utero, especially as these deformities have been so often found during early periods of fœtal life, when the presence of the liquor amnii would protect the limbs from being acted on by these mechanical causes.

The first appearance of non-congenital talipes is frequently observed during dentition, or after convalescence from some infantile disease, especially of spasmodic character. The loss of the use of the limb or limbs is at first often ascribed to paralysis or to general debility; but, as the child gains strength in every other part of the frame, one or both heels are found to be drawn up, and we have T. equinus; or a turning in of the toes is observed, and T. varus is present; or, as in other cases, T. valgus or T. calcaneus may result. Dr. Little has observed these several forms of club foot, the history of which was preceded by infantile diseases such as are here named. And he gives cases in which talipes has been thus originated by disturbances of the organic system of nerves, not merely in infancy, but at later periods of life, even after the age of puberty. He cites instances of hysterical young women who had previously enjoyed the perfect use of their limbs, and yet, through spasm of the gastrocnemii, and anterior and posterior tibial muscles, they have been ever after afflicted with club foot, having all the characteristics of the congenital forms.

Dr. Little's doctrine is, that any cause, whether paralytic or spasmodic, by which the equilibrium between different sets of muscles that are naturally antagonists is disturbed, may produce club foot. Other distortions more or less resembling club foot are often produced by the cicatrization after burns or ulceration, or by too long confinement of the limbs in a particular posture, or, indeed, any agency which seriously disturbs the antagonism of the muscles. The adoption of this etiology will lead to a more rational treatment of all these

distortions than the indiscriminate employment either of tenotomy or mechanical apparatus and bandaging, or both, however valuable these means may be regarded in the cases to which they are appropriate.

The plan of treatment in these non-congenital cases should be decided upon the principles of rational medicine and enlightened surgery; and such deformities call for as careful discrimination of the true pathological state as is demanded in other cases of organic or functional malformation. A case of talipes originating from paralysis of the anterior muscles of the leg, will, when it occurs after birth, require the same treatment as is adapted to paralytic affections in any other part of the body. Hence, when the distortion results from active, permanent, and involuntary contraction of the muscles of the calf, the attention of the surgeon should be directed to the central organs of the nervous system, the brain and spinal cord; or, in other cases, he will find the incident and reflex functions of the nervous system which have disturbed the equilibrium of the muscles of the foot in the chylo-poietic or other viscera, and medicate accordingly.

Dr. Little's work, because of his inculcating these views at length, is the more worthy of confidence. So, also, he discriminates clearly between the cases which can be cured by mechanical means alone, and those in which tenotomy is demanded in order to render any such apparatus available for permanent benefit. I must refer the surgical reader to his work as one which will amply repay a perusal.

Dr. Heber Chase, of Philadelphia, is strongly opposed to the practice of indiscriminate tenotomy in club foot, now becoming so common in this country. He believes that a large majority of cases are curable by mechanical means rightly and carefully directed, without the aid of the knife. His instrument for the primary treatment of varus and valgus, which is novel in structure and very simple, is described and figured in a paper published in the *American Journal of the Medical Sciences for January*, 1841, in which the author has given the results of a number of cases. He contends, in his lectures on deformities, that the system of treatment advocated by him is capable of restoring the foot to its normal shape with more certainty, greater ease to the patient, and in less time, than any of the methods of extension practised after tenotomy. He also contends that there remains less disposition to relapse.—REESE.]

D.

[DEFORMITIES. Dr. Mutter, of Philadelphia, has the merit of having been the first in America to perform Dieffenbach's operation for removing a deformity of the mouth. (See *Amer. Jour. for* 1837, No. 40.) And in the 51st number of the same journal, the same surgeon reports a case of rigidity of the masseter muscle relieved by an operation. In this operation Dr. Mutter has the priority, although it has since been performed by Dr. Carnochan and Dr. Schmidt, of New-York, and also repeated in Europe. Dr. Mutter has succeeded in three cases.

In the American Journal for July, 1842, Dr. Mutter has published an original operation for removing a hideous deformity occasioned by a burn, illustrated with plates, and which will be found to be highly creditable to his skill and science.

Dr. Pancoast, of Philadelphia, has successfully operated upon a number of cases of immobility of the lower jaw, with extensive adhesions following mercurial ulcerations of the cheeks and gums, and accompanied by frightful deformities.

Dr. Mutter has also reported in the American Journal for 1842 a case of deformed leg, in which resection of the bone was preferred to amputation, with the happiest result.—REESE.]

[DISLOCATION. An instance of a compound dislocation of the sternal end of the clavicle backward is related by Mr. Tyrrell. (See *St. Thomas's Hospital Reports*, vol. i., p. 261.) It was caused by the fall of a heavy mass of earth, which drove the sharp end of a pickaxe against the chest. When the finger was introduced into the wound, the great pectoral muscle was found torn from the clavicle, and the finger could be passed as far outward as the coracoid process, and inward to the trachea. The greater part of the interarticular cartilage remained in its place. There was emphysema below the clavicle and over the sternum, and difficulty of breathing. The shoulders were brought back with straps attached to a backboard, and the bone readily resumed its place. The elbow was brought forward and bound to the side. The case terminated well.

Sir Astley Cooper informs me that the dislocation of the os humeri on the dorsum of the scapula is most readily reduced by bending the elbow, putting the hand behind the neck, and then inclining the lower end of the humerus backward.

Mr. John Macdonnell has published the case of a simple and complete dislocation of the astragalus from the os calcis and navicular bone upon the dorsum of the latter, without disturbance of the relations between the tibia, fibula, and astragalus, and without fracture of any of these bones. (See *Dublin. Journ. of Med. Science*, vol. xiv., p. 235, &c.)—C.]

[Dr. George W. Norris, of Philadelphia, has published a case of complete luxation of the spine without fracture, in which the fifth and sixth cervical vertebræ were involved, for which see Amer. Journ. Med. Sciences, vol. i., new series, p. 336.

Dr. J. Watson, of New-York, reports an interesting case of dislocation of the patella on its axis in the N. Y. Med. and Surg. Journ. for 1840, together with observations on the case of a valuable character, which is also referred to since in the Cyclopædia of Anatomy and Physiology, published in Great Britain.

Dr. Lehman reports, in the Amer. Journ. for 1827, a case of a sailor who could dislocate his shoulders at pleasure, and was in the habit of exercising this piece of discretion when he wished to avoid any laborious or disagreeable employment. The luxation was always effected downward and inward, and was readily produced by the voluntary contraction of the muscles whenever he had any motive to perform the volition. It was in every case readily reduced in the usual

way; and although he was able at once to use the limb at his work, yet, as he was directed by the surgeons who were called to him to wear it in a sling for a few days as a measure of precaution, he was wont to avail himself of this course, and thus indulge his indolence. This must be superadded, therefore, to the list of feigned diseases; for, although self-induced, he was not able to effect reduction without surgical assistance. The case, however, must be a very rare one, probably unique.

Dr. Gross has inserted a note, in his late Philadelphia edition of Liston's Elements of Surgery, on congenital luxation of the hip-joint, which, though rare in this country, has been witnessed by Dupuytren in twenty-six cases; and he found it to be incurable.

Dislocations at the hip-joint, in which the head of the femur takes other directions than the four ordinarily laid down in the books, are often observed. Dr. Willard Parker, of New-York, relates an interesting case, in which the head of the bone was found in the perineum. See *N. Y. Gazette*, vol. i., 1841.

A NEW FORM OF LUXATION AT THE SHOULDER.

Professor Parker, of New-York, was called by Dr. R. Campbell, of Pittsfield, Mass., to see a patient who had luxated the right shoulder. He was twenty-two years old; good constitution; was at work at the time of the accident in a woollen factory. The luxation was produced by the hands being caught between the belt and drum while the machinery was in rapid motion. The hand was carried under the drum, being strongly pronated, and the head of the humerus seemed to have been strongly twisted; the capsular ligament was rent, and the head of the bone was felt under the scapula; the rotundity of the shoulder lost; and the arm and forearm were lying diagonally across the thorax.

This luxation was reduced into the axilla, and then from this position the head of the bone was readily carried into place.—REESE.]

E.

[EAR. Mr. Edward Cock has examined the temporal bones of five children, who died of strumous diseases of the thoracic and abdominal viscera in the Asylum for the Deaf and Dumb. In three instances, one or both ears were the seat of scrofulous ulceration, affecting the tympanum and meatus externus, with partial destruction of the membrana tympani. In one case, the cavity of the tympanum, together with the mastoid cells, was completely filled with the thick, cheesy deposite of scrofula, while a similar affection pervaded the whole cancellated structure of the petrous bone. The connexions of the ossicula were destroyed, but the bones themselves remained entire. In all the cases examined by Mr. Cock, the petrous portions of the temporal bones exhibited more than the usual varieties of size and shape. In some, the bone was so deficient in particular spots as barely to cover the internal cavities, while in others there was a preternatural osseous development. In one instance, the petrous bone of a child twelve years old exceeded in size, hardness, and compactness of structure that of an adult. One malformation, discovered in two cases, consisted in a partial deficiency of two of the semicircular canals. Their extremities opening into the vestibule were perfect, but the central portions were impervious, or, rather, did not exist at all. In one case the scala tympani was terminated at its larger extremity by a bony septum, which separated it from the tympanum, and occupied the situation of the membrane of the fenestra rotunda. With the exception of these malformations, and the scrofulous affections of the tympanum already mentioned, which were probably of recent occurrence, no deviation from the healthy state could be discovered in either of the five subjects examined. The Eustachian tubes were pervious; the bones, muscles, and membranes entire and natural; the labyrinths were filled with their transparent fluid; and the auditory nerve presented no peculiarity. The chorda tympani existed in each of the cases; but the integrity of all its little filaments passing into the tympanum, and requiring a microscope for their dissection, could not be vouched for. (*E. Cock* in *Med. Chir. Trans.*, vol. xix., p. 152.) In a case dissected by Mr. Dalrymple, the aqueduct of the vestibule was large enough to admit a small probe; and, in a later examination of the ear of a child who died in the Asylum for the Deaf and Dumb, Mr. Cock could find no vestige of the fenestra rotunda on either side, the usual situation of the membrane being occupied by solid bone. The temporal bones were exceedingly large, though soft and spongy. The cavities were extraordinarily capacious, and the Eustachian tubes three or four times larger than common. On one side, the aqueduct of the vestibule readily allowed the passage of a large bristle, but on the other side the canal could not be traced through the bone, although its two extremities were more than usually expanded. In one tympanum suppuration had taken place. (*E. Cock, ib.*)—C.]

[In the United States there have been few surgeons who have distinguished themselves by their success in the treatment of diseases of the ear. Deafness is a less frequent disease in this country than in Europe, but cases are nevertheless sufficiently numerous to deprive us of any justifiable excuse for the neglect which this subject has received from American surgeons. It is true that the repetition here of the methods of Kramer and other foreign writers have been much less successful than these transatlantic surgeons would lead us to hope. Still, however, there have been instances of similar success to those they record, and in sufficient number to encourage future efforts.

Dr. Cohen, of Baltimore, and Dr. Dix, of Boston, have for several years directed their particular attention to diseases of the internal ear, and to the investigation of the abnormal condition of the tympanum and Eustachian tube in cases of deafness. These gentlemen have employed condensing apparatus for administering the air douche through the Eustachian tube after the plan of Kramer and others. By the air and also the water douche, these gentlemen have acquired great tact in the diagnosis and treatment of ob-

structions in the tube and upon the tympanum. For the treatment of nervous deafness, the douche of acetous and sulphuric ether has in many instances been successful, but the proportion of cases benefited by the douche in this country is very much less than stated by Kramer.

There is reason to believe that, in minor affections of the ear, accompanied by temporary deafness, very great mischief is often done by the earpick, employed empirically by the patient himself. The little finger on each hand has been called the ear-finger, because of its adaptation to the office of clearing out obstructions in the external ear; nor should any smaller or ruder instrument ever be introduced except by a surgeon, who has his eye to guide him, aided by a speculum auris. The introduction of earpicks and pins into the external ear by patients is among the frequent causes of irremediable deafness. So, also, stuffing the ear with cotton, either with or without oil and other medicaments, is to be deprecated by all who would not hazard the loss of this important sense of hearing. The fibres of the cotton often become incorporated with the morbid secretions in the meatus, and find their way to the tympanum, and are not easily removed. Hence wool should be substituted in such cases, as not liable to this objection.

In the treatment of earache, however, which is often genuine otitis, and requires active depletion, local and general, suitable discrimination is demanded. But in those cases depending on a local morbid sensibility, without evident inflammation, it is common to stuff into the meatus a plug of cotton or wool moistened with oil, with or without a mixture of laudanum. This practice, when not absolutely injurious, is never useful. If it be expected to reach the membranum tympani with the anodyne oil, it should be poured into the external ear until it is full, which may be known by the cessation of the escape of bubbles of air from the surface of the oil after the ear is filled. A piece of wool may then be introduced into the meatus. This method of introducing olive oil, or the oil of almonds, into the ear, will often relieve deafness, when ascertained to be dependant on hardened cerumen. The injection of the oil, or of warm water, which is better, is greatly preferable.

In those examples of deafness arising from a deficiency or absence of cerumen, and, indeed, in cases of nervous deafness, and all others in which there is a want of sensibility in the organ, I have found early and permanent benefit by the kreosote mixed with oil of almonds, in the proportion of one part of the former to three of the latter. This mixture should be introduced upon a camel's hair pencil down to the tympanum, and, with suitable discrimination in the cases, will never do mischief, and often effect a cure. The reader will find in the article on this subject in the Dictionary most valuable matter, to which I have here prefixed what is important in Mr. Cooper's last edition.

Dr. Mussey, of Cincinnati, has operated, by perforating the membrane of the tympanum, for deafness, accompanied by a closure of the Eustachian tube, in six cases. Only one of these patients was restored by the operation. In the other five cases, the deafness, in all probability, was not dependant on the closure of the tube, although this state coexisted.—Reese.]

[ECTROPIUM. Juengken describes a plan, which has been adopted by Jaeger himself, and was practised a hundred years ago by Platner (*Instit. Chir.*, § 582), and even recommended a century before this author by our countryman Bannister. Heister and Dionis notice it still more circumstantially. (See *Middlemore* on *Dis. of the Eye*, vol. ii., p. 787.) It consists in detaching the everted eyelid from the cheek, or superciliary ridge, at every point excepting the angles, by introducing a sharp-pointed, double-edged knife through the conjunctival surface, near the inner angle, bringing it out through the skin, and conveying it across to the outer angle. A portion of the thickened conjunctiva, or a triangular piece of the lid, may be first removed, if necessary. The detached lid is then to be accurately fixed in contact with the globe, and the skin of the cheek drawn towards the eye, and kept in that position with adhesive plaster, compresses, and bandage. (*Handbuch*, &c., p. 696.) Dieffenbach makes an incision through the skin and orbicularis nearly parallel to the edge of the lower lid, beginning two or three lines from one angle, and terminating at the same distance from the other. It is one line from the edge of the lid at its two ends, and two or three lines in the middle. He turns up the small flap of skin, and dissects through the lid to the conjunctiva, which he divides to the extent of the external wound. With a hook he draws the external margin of the divided conjunctiva into the wound of the skin, and keeps it and the teguments together with sutures. (See *Chir. Erfahrungen über die Wiederherstellung Zerstorter Theile, &c., von J. F. Dieffenbach*, p. 127, Berlin, 1830; also Autoplastic.)—C.]

[EMBRYOTOMY. In the Philadelphia Practice of Midwifery, by Dr. Meigs, an anomalous case is reported, in which that gentleman employed a peculiar trocar and forceps for the extraction of the fœtus, which the surgical reader will find to be of great practical importance. This same patient has been twice subjected to the Cæsarean section by Dr. Gibson since Dr. Meigs's operation of embryulcia, and the case will be found under the appropriate head in this Appendix.—Reese.]

[EMPYEMA. In the Amer. Journal of Med. Sciences, Dr. Pancoast, of Philadelphia, has published a paper on empyema, in which he describes a new plan of treatment, the success of which in the case reported is the best proof of its merit.—Reese.]

[EPISIORAPHY. Professor Geddings has published a monograph on the subject of sutures in the external labiæ of the female pudendum, which may be found in the American Journal for 1840. Since then the operation has frequently been repeated in this country with success for procidentia uteri. Dr. Eve and Dr. Dugas, of Georgia, have both practised it successfully.—Reese.]

[EPISPADIAS. Dr. Mutter has cured two cases of this disease by the usual operation. Dr. Mettauer, of Virginia, has lately published a paper on this malformation, including hypospadias, which is of an eminently practical character. It may be found in the Amer. Journal of Med. Science for July, 1842.—Reese.]

[ERYSIPELAS. The application of the nitrate of silver in substance, or in the form of a lotion, so as to blacken the part, appears to have considerable power as a means of checking the peculiar action of the vessels on which erysipelatous inflammation depends. It tends to repress the effusion of serosity in the cellular tissue; and, if applied beyond the erysipelas, will form an ob

stacle to its spreading in any particular direction. By forming a black line with it, the inflammation may thus be kept from running up the neck to the face and head. The use of nitrate of silver in erysipelas has been particularly insisted upon by Mr. Higginbottom. (*On the Use of Nitrate of Silver.*) In the early stages of erysipelas I have often employed it with advantage in the North London Hospital; but it should not be continued too long; for when it fails to lessen the distension of the cellular tissue with serosity, the fluid should be discharged by puncture or incision. Mr. Higginbottom directs the part to be first washed with soap and water, and then dried. The inflamed and surrounding skin is then to be moistened, and the nitrate of silver passed over it once, twice, or thrice, and more frequently, if rapid vesication be required. The part is then to be exposed to the air and kept cool.

Of the good effect of mercurial ointment as an application to erysipelas, I cannot speak from experience. Dr. M'Dowel has tried mercurial unction, and makes a favourable report of it. In Mercer's Hospital, it was found also to have considerable power in checking the disease. Two, three, or four applications usually sufficed, with other means. In most instances, the patients were salivated. (See *Dublin Journ. of Med. Science*, p. 6.—C.]

[EXCISION OF BONES. Dr. Thomas Harris, of Philadelphia, has excised the elbow-joint for caries for the first time in America, and with entire success. Dr. Warren, of Boston, has recently repeated this operation with the like result. Dr. Mutter, of Philadelphia, has successfully performed a similar operation, by excising the lower extremity of the humerus and the upper extremity of the ulna for caries. He prefers the incisions of White in all such cases.

Dr. Pancoast, of Philadelphia, has had extensive experience in the excision of bones. He has lately removed the elbow-joint for caries, following the plan of Moreau and Syme; and he has excised the upper radio-carpal joint, removing all the articular faces of the three bones, employing Barton's saw and Liston's forceps. He has also cut out the metacarpo-phalangeal joint of the great toe for caries. In all these operations he has had complete success.

In the eighth volume of the North Am. Med. and Surg. Journal, Dr. Alban Goldsmith relates a case in which he removed portions of three dorsal vertebræ for the relief of paralysis from fracture, and with partial success. The young man had been thrown from a horse, and he was almost universally paralyzed from the moment of the accident. At first the case was regarded as one of dislocation of the vertebra; but Dr. Dudley discovered a fracture after making an incision down to the bone, the base of the spinous process being driven in upon the spinal marrow. The operation was performed by Dr. Goldsmith for the purpose of removing the pressure from the cord, and he excised a part of the spinous processes of two vertebræ, half of the third, and the whole of the fourth of the dorsal vertebræ. The sensation partially returned, and for a time very great hopes were entertained, but ultimately the patient died, life having been protracted, however, for several months, and great relief meanwhile having been afforded to the paralysis. Had not the operation been so long delayed, there is good reason to believe it would have completely succeeded.

Dr. Norris, of Philadelphia, excised the astragalus in a case of simple luxation of this bone, and has published critical remarks upon this practice in the Amer. Jour., vol. xx., No. 40. In the article on Dislocation in this Dictionary, it will be seen that Dupuytren performed this operation in 1818; but numerous cases are on record which were cured by reduction, and others in which no permanent lameness resulted, even when it was found to be irreducible. The necessity for the excision in any case must be rare, and, indeed, such examples of luxation will be found but very seldom.—REESE.]

[EYE. Dr. J. C. Warren first described a case of accidental dislocation of the crystalline lens in the New-England Med. Journ. for 1811; and he also, in the same journal, called the attention of the profession to a rheumatic inflammation of the eyes, now universally recognised, but until then very little was known of its diagnosis.

Professor Dugas, of Georgia, relates a number of morbid conditions of the eye, in which it became necessary to destroy the organ. This he effected by passing a tenaculum through the cornea, and excising it with the straight bistoury, without touching the sclerotica. There can be little doubt that the removal of the cornea in this way should be preferred to the excision of the eyeball, which in many cases has been unnecessarily resorted to. Dr. Dugas seems to have used suitable discrimination in his cases; and the eye being lost, the deformity resulting from his operation was greatly diminished, while the removal of the cornea by his method is attended with no danger. No untoward symptom followed in any of his cases.

Dr. W. A. M'Dowell, of Louisville, Kentucky, has published in the Western Journal a paper on the eye, containing surgical and pathological observations of great practical value. I regret that my limits will permit me only to make this reference to an article which possesses both novelty and merit.—REESE.]

F.

[FINGERS, PERMANENT CONTRACTION OF.

Baron Dupuytren has made some interesting observations on this affection, to which each of the fingers, but especially the ring-finger, is liable. Most of the individuals who have this infirmity have been accustomed to make efforts with the palm of the hand, and to handle bodies of great hardness. When a tendency to the complaint begins, some difficulty is experienced in extending the fingers, and the ring-one soon becomes contracted; the carpal phalanx being first implicated, and the others afterward inclining in the same direction. In this stage, the flexion of the two adjacent fingers becomes more marked, but no knottiness is yet perceptible in front of, and around the cord on the palmar side of the ring-finger. Its second and third phalanges are straight and movable; the first is bent more or less to a right angle, and is movable on the metacarpal

bone; but it cannot be put into the straight position by the most violent efforts. Dupuytren refers to a case in which a trial was made to cure the patient by means of the application of different weights, which were increased up to 150 pounds without the flexion being removed.

When the ring-finger has become very much bent, the skin is thrown into folds, the concavity of which is towards the fingers, and the convexity towards the radio-carpal articulation. On first inspection, one might suppose the skin to be diseased; but this is not the case. A tense cord is felt on the palmar side of the finger; it extends towards the first phalanx, and may be traced to the upper part of the palm. When the finger is bent, it disappears almost entirely. If attempts be made to extend the fingers, the tendon of the palmaris brevis is felt to move, and the motion is propagated to the upper part of the palmar fascia. The patient is unable to grasp largish bodies; and if he try to take hold of them more forcibly, or an endeavour is made to extend the fingers, he experiences acute pain. The causes of this disease were formerly referred either to thickening and contraction of the skin, spasm of the muscles, disease of the flexor tendons or that of their fibrous sheaths, or some change in the articular surfaces and lateral ligaments. All was uncertainty, when Dupuytren had an opportunity of dissecting a hand in which this infirmity existed. A drawing having been first made of it, the integuments were removed from the palm and palmar aspect of the finger, after which the folds and wrinkles had entirely disappeared. From this it was clear that the disorder did not depend upon the state of the skin. As soon as the palmar fascia had been exposed, it was found to be tense, contracted, and shortened, and that from its inferior part cords or bands proceeded to the sides of the affected finger. On attempts being made to straighten the finger, M. Dupuytren observed that the fascia became tense. He then divided the prolongations of it extending to the sides of the finger. The contraction ceased immediately, and the finger assumed a very slightly bent position. In fact, the disease was ascertained to be owing to the extreme tension of the palmar fascia, brought on by a contusion of the palm, or the long-continued pressure of hard substances upon it. The plan of cure adopted by M. Dupuytren consisted in making a transverse incision, about ten lines in length, over the metacarpo-phalangian joint of the ring-finger. The skin was first divided, and then the palmar fascia. As soon as this had been done, the finger became straight, and could be extended almost as readily as in the natural state. After the operation, the hand was fixed with a bandage upon a piece of pasteboard for a few weeks, and the fingers kept extended. In one case M. Dupuytren made semicircular incisions—one at the base of the ring-finger, in order to divide the two digital and lateral prolongations of the palmar fascia sent to this finger; the other an inch and a quarter from the first, in the palm of the hand, for the purpose of dividing the digital prolongation at its root, and thus detaching it from the palmar fascia. (See *Dupuytren, Clin. Chir.*, t. i., art. 1.)

In a lecture delivered subsequently to the preceding observations, M. Dupuytren adverts to flexions of the fingers arising from other causes; as a previous wound of the palm known by the scar; alteration in the formation of the phalanges by disease, and unattended with the kind of cord observed when the palmar fascia is implicated; and a division of the extensor tendons with a cutting instrument, which parts, not being united again, leave the flexors without any antagonists. A contused wound, producing sloughing of the skin of the palm, may have the same result, if its edges be suffered to be drawn together, instead of cicatrization being completed by the formation of a new cutaneous texture. (See *Clin. Chir.*, t. i., p. 251.) Burns of the palm are frequently followed by this deformity when the preceding indication is neglected. Among other causes of permanent flexion, M. Dupuytren notices deformity of the articular surfaces of the phalanges, produced by the long-continued position of the fingers in certain employments, as in lacemakers, tailors, &c.; by wounds of the flexor tendons, or their displacement, in consequence of having been extensively laid open for the cure of whitlow. The wound of a joint may be another cause of contraction of the finger; and a gunshot-injury of the flexor muscles may lead to the same consequence. M. Dupuytren's observations on this subject seem to me equally original and valuable. The toes are also liable to a contraction, dependant upon a state of the plantar fascia corresponding to that of the palmar.

I have introduced the opinion of Dupuytren on the cause of such contraction, viz., that the bands hindering the extension of the finger were produced by a permanent contraction of portions of the palmar fascia. The same view was adopted by the late Mr. Henry Cline, and, as would appear from an extract taken from his lectures, and published in one of the volumes of the *London Medical Gazette*, even prior to the period when Dupuytren taught the corresponding doctrine. The former had also anticipated the latter in the practice naturally dictated by such contemplation of the cause of the deformity. MM. Goyraud and Velpeau, however, object to the explanation of the subject given by Dupuytren, because the digital slips of the palmar fascia terminate in, and are fixed to the base and sides of the root of each finger, while the diseased band is situated in the middle of the finger, and is often prolonged to the third phalanx. They both concur, therefore, in ascribing this contraction to the transformation of a part of the subcutaneous cellular tissue in front of the phalanges into a fibrous band. M. Sanson also believes that this is the ordinary case, and that the contraction of the palmar fascia is an exception. The treatment recommended by M. Goyraud consists in making a longitudinal incision through the skin, over each band, when extended, to separate the lips of the wound, to detach the fibrous cords by dissection, and to cut across them when thus detached from their connexions. (See *Gaz. Méd.*, No. xxxi. and xxxii., Août, 1835.) Sir Astley Cooper passes a narrow knife under the cord, which is cut through without dividing the skin. —C.]

[FISTULA. Thus the presence of a dead piece of bone or of a foreign body often keeps up suppuration, and the fistula continues for the discharge of the matter. When an abscess forms near the anus, the matter lodges, and the part is disturbed by the action of the sphincter—a *fistula in ano* is produced. Sometimes a fistula is produced by the continual discharge of some healthy secretion through a wound or ulcer, as exemplified in salivary, lachrymal, and urinary fistulæ. The lining of old fistulæ may assume the appearance of certain mucous membranes, though follicles and villi, like those of the intes

tinal canal, have never been observed in it. As Andral remarks, when most perfectly organized, it can only be compared to the most simple mucous membranes, such as those of the ureters, or lesser branches of the hepatic ducts. The lining of fistulæ, like mucous membranes in general, when not irritated, is pale and of a grayish colour; but, if affected with acute or chronic inflammation, it exhibits the same shades of injection and redness seen in a mucous texture. It is also liable to certain affections, which pertain almost exclusively to mucous membranes, as fungous growths, callosities, &c. The cellular tissue connected with the lining of fistulæ may become thickened, indurated, and scirrhous, just like the submucous cellular tissue in general. Finally, just as adhesions never take place between the different points of a surface lined by a mucous membrane, unless a solution of continuity has taken place in it, so the sides of a fistulæ cannot adhere together, and its cavity be obliterated, unless incisions be made to bring the textures and the membrane-like investment of it into contact. (See *Andral, Précis d'Anat. Pathol.*, t. i., p. 261.)—C.]

[Dr. Hayward, of Boston, has performed an operation for vesico-vaginal fistula, which, from its originality and success, is worthy of attention, as well as from its being the first instance in which this distressing malady has been cured in this country. It may be found described in the Boston Med. and Surg. Journal for 1839.

Dr. Mutter, of Philadelphia, has a valuable paper on the different operations for fistula in ano, in the thirty-second number of the Amer. Journ. of Med. Science for 1834.

Dr. J. Rhea Barton has cured a formidable case of salivary fistula by a modification of the seton, and making an artificial opening into the mouth from the duct for its passage by a new sinus.

Dr. Mutter has cured three out of five cases upon which he has operated for vesico-vaginal fistula. The operation he prefers will be described in his forthcoming work on Surgery, to which I am obliged to refer.

Dr. Pancoast, of Philadelphia, has had singular success in treating fistulæ in perineo consequent upon urethral stricture. In some of his cases there were many fistulous openings, with callous thickening of the subcutaneous tissues of the scrotum, perineum, and nates, greatly obscuring the anatomy of the parts, complicated, in some cases, with enlargement and disorganization of the prostate gland. His plan is to introduce a silver catheter down to the stricture, open the raphe of the perineum near to the anterior margin of the sphincter ani, and from this point make a transverse incision, running a little obliquely backward, of an inch or more in extent, towards the tuberosity of the ischium. He thus readily reaches the membranous part of the urethra. In the incisions he has never found it necessary to apply a ligature to a single vessel. He then cuts through the stricture at the end of the catheter into the membranous part of the urethra on the plan of Mr. Shaw. He now directs the patient to urinate, and thus discovers the passage to the bladder through the wound, and introduces along the membranous portion of the urethra a probe-pointed silver director, made large for the purpose, along which he carries the end of the silver catheter till it reaches the bladder. The soft parts are then brought over it by suture, and in most cases he is able to effect union by the first intention. Dr. Pancoast does not remove the catheter for six or seven days, when he finds no difficulty in introducing another. He has tried Sir C. Bell's plan, by pushing in a bistoury in front of the prostate, and cutting downward, forward, and outward; but as there is not retention of urine sufficient to keep the membranous portion of the urethra distended, this method does not answer.

In the twenty-sixth volume of the Boston Med. and Surg. Journal, Dr. E. H. Dixon, of New-York, reports an interesting case of fistula in perineo and artificial anus coexisting in the same individual, and resulting from an abscess in the prostate gland.

Dr. J. Rhea Barton has published in the Amer. Journ. for 1840 the particulars of a successful operation he performed for the cure of a recto-vaginal fistula, which is creditable to his skill and talents.

Professor Parker, of New-York, in operating for fistula lachrymalia, has introduced an improvement, by employing a narrow-bladed knife for the incision, upon the side of which is a groove, so that it combines in itself the advantage both of the knife and director. The incision being made with this knife in the usual manner, it is easy to pass the style along the groove while the knife remains, and thus complete the operation with greater facility than by the ordinary method. The same surgeon has also constructed a bistoury with a similar groove on its side as a director, along which a probe may be passed, and which is well adapted for exploring purposes, as in obscure tumours, and in searching for foreign bodies.

FISTULA IN ANO.

In the notice of the operation for this disease, Mr. Cooper makes no mention of Dr. Physick's sheathed bistoury, or the instrument of Cruickshank, but still directs the use of the director and probe-pointed bistoury. Now, where there is no opening between the gut and sinus, as in incomplete fistula, it is necessary to make one, and the probe-pointed instrument will not answer in these cases. Dr. Physick's sharp-pointed bistoury, with a silver sheath covering both its point and cutting edge, can be introduced in the sinus or the gut until it reaches the point at which the one is to be opened into the other, and then, by removing the sheath, the puncture and incision are both easy. Mr. Cruickshank's bistoury has a movable stilet, which can be protruded or retracted at pleasure, and fulfils the same intention as the instrument of Dr. Physick, by combining in itself both the sharp and the probe points. The latter is preferable, however, because its sheath conceals the cutting edge, and prevents any wound during its introduction.

For the operation for fistula in ano by the ligature, in the cases in which this is preferred, Dr. Gibson has constructed an instrument which possesses many advantages, and may be found described in his late work.

Dr. Eve, of Georgia, has had uniform success in curing this disease by incision; he only dresses the wound once to prevent adhesion, and afterward relies upon bathing and the daily evacuation of the rectum.—Reese.]

[FRACTURES. Dr. J. Rhea Barton, of Philadelphia, has introduced into the Pennsylvania Hospital the treatment of compound fractures of the leg by bran-dressing, which has been ever since adopted in that institution with the most satisfactory results. It is described in the Amer.

Journ., new series, vol. i., p. 327, and also in Dr. Norris's edition of Liston. The limb is fixed in a fracture-box on a bed of dry bran, and simply surrounded and enveloped in the same material. This dressing is soft and grateful to the patient, keeps up equable and sufficient pressure, while the bran expands when moistened by hemorrhage, and the pressure is thus increased. It may be removed and changed by a spatula or syringe, and again applied as often as it may be called for, and without disturbing the limb or inflicting pain. In hot weather, this dressing of clean bran is spoken of by Dr. Norris as possessing great advantages, by absorbing the perspiration and hemorrhage, and preventing the fetor which is apt to attend such cases, and taint the ward of the hospital.

Dr. W. H. Van Buren has a paper in the Amer. Journ. for 1840, on the immovable apparatus, and its therapeutic application to fractures, and various other surgical diseases, which possesses great merit.

Dr. Mott has treated a number of cases in which fracture of the cervix femoris had occurred, and has uniformly found that, in early and middle life, union may be expected, even when the fracture is within the capsular ligament. In aged persons, he has never known the bone to unite after such an injury.

In fractures of the femur, he prefers the double-inclined plane in all cases, even when the cervix is broken; and he recommends this plan after trying Pott's, Desault's, Physick's, and Boyer's methods in repeated examples. He finds that the best limbs can be made by this flexed position, and it is most comfortable to the patient.

Dr. Mott has been very successful in the treatment of ununited fractures by the introduction of a seton, and has three times employed it in the thigh with complete success. He takes this course whenever time, frictions, and irritating the ends of the bones by walking in splints do not effect consolidation.

In one case of ununited humerus, when the fracture-ends were at a little distance from each other, and when the seton had been worn for six months without benefit, he succeeded by exsection In other cases, after failing to succeed by exsection in ununited fractures of the arm, he has subsequently cured the patient by the seton, and in the humerus has found this remedy almost uniformly successful.

In three cases in which the fractured tibia had failed to unite, he has effected a cure by the seton, and one of these was of more than twelve months' standing. In another example, after complete union had been effected by the seton, the patient fell and fractured the bone at the same place. On subjecting him to the ordinary confinement, the cure was as early obtained as though it had been a primary fracture.

Dr. Mott directs that the seton in these cases should be passed directly between the ends of the bones; for if it merely pass beside the fractured ends, even though in contact, it will not succeed; and hence, when the bones are closely united by ligament or other tissue, a passage must be bored or drilled through, to admit the passage of the seton. In general, the time for continuing the seton will be from one to two months, though occasionally a longer time is required. So soon as union has commenced, which is known by the firmness acquired by the limb, Dr. Mott commences the withdrawal of the seton by removing a thread every two or three days; and by the time all are thus removed, the cure is found to be complete.

Professor Parker, of New-York, has treated successfully a case of fracture of the cervix femoris within the capsular ligament. He employed long splints. It was in a female at 60, who had enjoyed excellent health. The limb was but little shortened, and the motions of the joint but slightly impaired. The patient having since died, the femur has been obtained, and exhibits complete osseous union within the capsule. The bone and its fellow are preserved in the museum of the College of Physicians and Surgeons, New-York. I have witnessed two cases of a similar result, in which the seat of the fracture was manifestly within the capsular ligament; and though both patients are still living, the evidences of osseous union are conclusive. Neither of them was as far advanced in life as Dr. Parker's case, one of them being 76, and the other 52 years of age.

Dr. J. C. Warren has treated 38 fractures of the cervix femoris by the flexed position, and he reports 30 cases of success, a proportion far beyond general experience, and argues well for his method, whether these fractures were within or without the capsular ligament.

For twenty years he reports having treated fractured thighs with great success, employing extension and counter-extension by means of Desault's apparatus improved.

Dr. Isaac Parish, of Philadelphia, has cured a case of ununited fracture by friction of the ends of the bones. (See *Amer. Journ. for August*, 1834.)

Dr. Eve, of Georgia, has used the immovable apparatus of Sartin and Velpeau in more than 20 cases of fracture and sprains of the wrist and ankle, with the most gratifying results. He prefers the dextrine, after having tried flour and starch often enough to judge of their comparative merits.

Dr. J. Rhea Barton has met with fractures of the os calcis, in which the fragment to which the tendo Achilles was attached was forcibly drawn up by the contraction of the gastrocnemii. The foot being extended permanently by bandages, an osseous union of the fragments has been obtained in two cases; and though the broken fragment is prominent, and the tendon shortened to correspond, the patients have recovered without detriment to the motions of the limb.

Dr. George W. Norris, of Philadelphia, reports a case of ununited fracture of the humerus of four years standing, cured by the application of caustic potash, in the Amer. Journ., vol. xxiii., p. 283. The same surgeon has published a valuable paper on the occurrence of non-union after fractures, its causes and treatment. It may be found in the same journal, vol. iii., No. 5, new series, 1842.

Dr. Nathan R. Smith, of Baltimore, has invented an instrument for fractures of the thigh and leg, which is found by experience to possess extraordinary advantages, especially in the management of bad cases. It is concave, and adapted to the straight or flexed position of the limb, effecting extension and counter-extension to any desirable extent, and he has availed himself of the advantages derived from suspending the limb since 1827, and for which his apparatus is adapted. I regret that my limits will not allow a full detail of the points of merit which Dr. Smith's instrument possesses, but which obviously render it superior to any and every other, so that, wher-

ever it is known, this apparatus is preferred to any other.

Dr. George Fox, of Philadelphia, introduced into the Pennsylvania Hospital, in the year 1828, an apparatus for fractured clavicle, which is described minutely in Dr. Norris's edition of Liston's Practical Surgery, and which is every way preferable to Desault's. Indeed, to this latter there are many and forcible objections, by reason of which it is but rarely applied in America.

Dr. J. S. Heard, of New-York, has published in the New-York Med. and Surg. Journ. for October, 1839, a report of cases of ununited fracture treated at the New-York Hospital. In this report, the practice introduced by Dr. J. Kearney Rodgers, of New-York, is illustrated by a number of cases, all of which were completely successful.

Dr. Rodgers was led to adopt this course by having a case under his care which had resisted several modes of treatment, including two trials of the seton. Having removed the ends of the bone by excision, he found that the fragments were separated from each other an inch and a half, and it appeared impossible to bring the ends into contact. He then drilled a hole into the medullary cavity through the shell of each end, and passed a silver wire through these holes; and, having thus coapted the fragments, the ends of the wire were drawn through a canula which remained in the wound. He thus secured firm osseous union, and Doctors Mott and Cheeseman have since then repeated this method of treating bad cases with entire success. Mr. Liston and other surgeons, some of them in our own country, have condemned this practice; but as the only cases in which it has been tried have been unfavourable examples, and to which none of the other methods were adapted, some of them having been tested in vain, and as every case has succeeded, the merit of the operation is unquestionable. It is a modification of Mr. White's operation, and will succeed when this fails.—Reese.]

[FRAGILITAS OSSIUM. For the following cases, detailed at length, reference may be had to Dr. Gibson's late work.

The boy spoken of by Mr. Cooper, in the Dictionary, as a patient of Dr. Gibson, after having twenty-four fractures of different bones, has since deceased, by reason of a partial dislocation of the first and second vertebræ of the neck, after an illness of fourteen weeks.

Dr. Mettauer, of Virginia, reports the case of a citizen of Petersburg, Virginia, whose brittleness of the bones was so great that he frequently fractured the humerus, radius, ulna, and clavicles in giving blows, he being habitually pugnacious. Dr. Mettauer states that the tibia, fibula, and femur have been broken in his case several times from a sudden twist of the body, and from efforts to save himself from falls. His thighbones have been broken when attempting to get on horseback, and his ribs have been fractured from equally slight causes. He often said that he believed he could break the bones of the forearm by pressing them between the thumb and forefinger. So frequent were these accidents, that his domestics became expert bone-setters, and frequently managed his fractures. His recoveries were very rapid, reunion being readily effected, and very seldom was it necessary to confine him longer than three weeks after either of his fractures.

Dr. Elkinton records a case in which muscular action was of itself sufficient to fracture the bones, those of both arms above the elbow having been broken during a fit. Dr. Hendry, who attended the same patient, testifies that his bones were frequently broken by slight exertion, and in all cases they speedily reunited.

Dr. Goddard has a patient whose bones have been broken fourteen times, though now only twelve years old, and had fractured his thigh three times before he was four years of age, by falling from a step six inches high. This brittleness of the bones was a family complaint in this instance, for his mother had her thigh-bones broken six times; while her brother, at thirteen years old, had suffered nine fractures of the thigh and two of the arm, besides having one of his hip-joints dislocated. These persons are short of stature, and have small bones, but in other respects have good health.—Reese.]

G.

[GANGLION. Dr. Eve, of Georgia, has had extensive experience in the treatment of these tumours, and after trying incisions, extirpation, and puncture, prefers the method of acupuncturation as recommended by Velpeau, and afterward relying on pressure for their radical removal. The use of the needles is found to give very little pain.—Reese.]

[GANGRÆNOPSIS. In the *American Medical Recorder for July*, 1827, Dr. Jackson, of Northumberland, has published a paper containing a number of cases, with remarks on a disease of children, which he proposes to call *gangrænopsis*; and in the *Amer. Journ. of the Med. and Phys. Sciences, vol.* v., Dr. Webber has furnished a detail of several interesting cases of this gangrenous erosion of the cheek. Dr. W. has had the opportunity of witnessing four instances in the course of two or three years; three of the milder kind, and one of the most severe form, answering to the *nomer* of Burns. Case 4 being the most minutely drawn up, I shall here insert it, as a suitable appendage to my article on *caries of the jaws of children*. "This case occurred in September, 1828, in a little girl 10 years old. It ensued upon typhus, in which diarrhœa had been a troublesome symptom. About the fourteenth day, when the fever was apparently beginning to abate, she complained of a feeling of soreness and pain in the left cheek, not far from the angle of the mouth. The part was slightly swollen, somewhat hard, and reddish, like the commencement of a bile. Volatile liniment with laudanum was applied, and the redness disappeared, though the swelling continued, being, however, less hard, and rather more diffuse. A day or two after aphthæ appeared in the mouth and fauces, for which a gargle of diluted muriatic acid was employed. She complained, however, of the cheek's being hotter and sorer, and the swelling had evidently increased. On the inside of the cheek it protruded in a ridge between the teeth. Lead-water was used externally as a constant application, in addition to the occasional use of the

liniment above mentioned, and the inside of the mouth was frequently touched with honey, acidulated with muriatic acid; small quantities of wine were given, and one fourth of a grain of sulphate of quinine thrice a day; also small doses of Dover's powder to regulate the bowels, still rather too loose, and to procure sufficient rest. The cheek, nevertheless, continued to swell, and the breath became very fetid. The aphthæ disappeared in a day or two; but upon the most prominent part of the internal swelling of the cheek was a kind of flabby pustule or blister, seemingly beneath the whole thickness of the internal integument, which over the swelling was opaque, and of a dirty white colour. This broke the same evening, discharging a small quantity of fetid fluid, and leaving a sloughing appearance of its membranous covering. It was repeatedly touched during the night and the following day with a strong preparation of muriatic acid and honey, sufficiently strong to corrugate the sloughing membrane, and make it settle down below the level of the surrounding parts. This, it was hoped, would put a check to the diseased action, and cause the slough to separate. Notwithstanding, it continued to increase during the subsequent night, and on the next morning had nearly reached the angle of the mouth, which looked dusky, and approached to a state of gangrene.

"An eminent practitioner from a distance met me in consultation this morning, and advised carrot and fermenting poultices with charcoal over the cheek, a small blister externally over the angle of the mouth, and one on the inside of the cheek, of a size sufficient to cover the slough and the surrounding sound edges, while the internal remedies were continued in increased doses. The disease, however, proceeded with redoubled rapidity. Gangrene in undistinguished blackness passed in a few hours across the external blister, and at the same time came through the cheek, opposite to the point on the inside first attacked. In spite of the assiduous application of the poultices, these spots spread so as to coalesce in the course of the night, and by the next morning involved most of the unattacked portion of the cheek. The case was now deemed hopeless, and dissolution was soon expected. The fetor being excessive, with a view to lessen it the part was covered with a cloth wet with a solution of the chloride of lime (bleaching powder). This lessened the rapid spreading of the gangrene so much, that for hours it seemed almost entirely stationary, but did not become wholly so, though it progressed very slowly till it had covered the whole of the swelling existing at the commencement, reaching almost to the lower eyelid, over the membranous part of the nose of the same side, the septum, two thirds of the lips, and half of the chin, including all the cheek down to below the under edge of the lower jaw, and backward nearly to the ear. The parts were completely sphacelated, and had nearly separated; when, at the expiration of twelve days from the first appearance of danger, the little patient died. All the peculiar symptoms of the fever had entirely subsided long before her death."

I have had several opportunities of witnessing this frightful disease, but in all the cases I saw, it could be traced to the injudicious use of mercury. In two of them the whole cheek sloughed off, leaving the carious bones and the internal structure of the throat exposed, before they terminated fatally.—Reese.]

[GUMS, INFLAMMATION AND ABSCESS OF. *Gumboil. Parulis.* Inflammation of the gums mostly arises from the irritation of carious teeth, but sometimes from necrosis of a part of the alveolary process, or from the splintering of it occasioned by the extraction of a bad tooth. Sometimes it originates from exposure to cold, and in other instances from mechanical irritation. When the inflammation, arising from the irritation of a decayed tooth, cold, and some other causes, proceeds to suppuration, the case is then an abscess, here termed a *gumboil.* The treatment consists in making an early puncture for the discharge of the matter, and, after the subsidence of the inflammation, in extracting any bad tooth concerned in keeping up irritation. The mouth is to be frequently cleansed with an astringent gargle. If a fistula form in the gums, it is to be freely divided, and touched with the nitrate of silver, care being taken, however, before resorting to this measure, to remove any carious tooth, splinter, or dead portion of bone, which latter proceedings will generally supersede all necessity for laying open the fistula.—C.]

[GUMS, TUMOURS OF. A very common disease is a thickening of the gums at some particular point, which puts on the form of an excrescence, and generally assumes a hard, callous nature. Some of these swellings are connected with the periosteum or bone, and are disposed to acquire a malignant character; frequently, after they have attained a certain size, the neighbouring part of the bone becomes altered and softened. Other tumours of the gums are merely excrescences from the fibro-vascular texture of these parts, not penetrating deeply, not connected with the bone, periosteum, nor sockets of the teeth, and not malignant. The excrescence of the gums, then, termed *epulis*, is of very different character in different cases; but, as many tumours of the gums, apparently trivial at first, become fatal diseases in the end, if neglected in their beginning, the rule in surgery is to attempt their extirpation before they have made considerable progress.

On this subject Sir Charles Bell has made some interesting remarks. "We see (says he) a small tumour of the gums, stationary for a long time, and claiming no attention, at last forcing its way into the bones of the face, filling up the cells and the cavities of the nose, pressing out the eyes, and rising at last upon the base of the brain itself," so as to destroy the patient. The worst diseases of the gums, according to Sir C. Bell, do not come from the irritation of a bad tooth. "We see a carious tooth attended with ulcer and gumboil, and abscess in the jaw; with fungous tumour of the gums; even with necrosis of the jaw. We find the inflammation from the same source amounting in severity of pain to that of tic-douloureux. But these are of no account compared in danger with this tumour of which I am treating. This more formidable disease begins when the adjoining teeth are apparently sound, and when we cannot trace it to any common source of irritation. This tumour first shows itself in a small, hard prominence of the gum, shooting out between two of the teeth; and the teeth being good is an unfavourable circumstance; for when they have become loose and are displaced without being themselves diseased, it implies that the cause is deep, and not to be removed by pulling out the teeth. If the teeth be carious and originally in fault, we have a reasonable expectation of arresting the progress of dis-

ease by removing the teeth; but when, independent of the teeth, the tumour has its origin in the membrane of the fang or in the socket, we cannot hope to extirpate the disease without removing the whole system of parts," the tooth, the gum, and the adjacent portion of the jaw. (See *Sir Charles Bell's Surgical Obs.*, p. 413, 8vo, Lond., 1816.) A perpendicular division of the alveolary process is to be made at a prudent distance from each side of the tumour, and to the requisite depth, with a fine saw, any teeth in the way of its action being previously extracted. Then, with a strong pair of forceps, the portion of bone between the two fissures is to be broken off. The bleeding, which is copious, may sometimes be stopped by compresses dipped in the tincture of muriated iron, but frequently requires firm and long-continued pressure with the hands of a succession of assistants, or even the actual cautery.

The soft and more superficial kinds of epulis may be extirpated with a scalpel, care being taken to let the excision be sufficiently free and deep, and then to scrape the alveolary process, or rub the bottom of the wound with nitrate of silver, which will generally stop the hæmorrhage, and lessen the chance of a return of the excrescence. When the disease recurs often, as it did six times in a case mentioned by John Hunter, the removal of the parts must either have been imperfect, or the tumour cancerous, as happened in two examples which fell under his observation. (See *J. Hunter on Natural Hist., &c., of the Human Teeth*, p. 188.)—C.]

[GUNSHOT WOUNDS. Dr. Paul F. Eve, of Georgia, has politely furnished me the particulars of a case of gunshot wound, in which one ball made six wounds. It occurred in a so-called "affair of honour," in which the ball passed through both thighs, and the right leg having been thrown forward at the moment of receiving the ball, it passed between the scrotum and perineum, inflicting a wound upon both. This ball thus made two wounds in each thigh, one in the scrotum, and one in the perineum. The patient nevertheless recovered, and is now well.—REESE

H.

[HÆMATOCELE. (From αἷμα, blood, and κήλη, tumour.) A swelling of the scrotum, proceeding from, or caused by blood.

The term has sometimes been applied to every kind of extravasation of blood about the scrotum and spermatic cord, but at the present day it is usually restricted by British surgeons to a collection of blood in the cavity of the tunica vaginalis. Extravasation of blood in the cellular tissue of the scrotum and spermatic cord, or within the structure of the testicle itself, Pott, however, arranges with hæmatocele. This last swelling is generally pyriform, like hydrocele, but is distinguishable from it by its greater weight and firmness, its want of transparency, its obscure fluctuation, and its cause, which is usually a blow upon the scrotum, or an accidental puncture of some vessels of the testicle or tunica vaginalis in tapping a hydrocele. When the latter membrane has been long or much distended by the serous fluid of hydrocele, it becomes thickened, and its vessels, especially those of its inner surface, enlarged, and even varicose. If one of these lies in the way of the instrument with which the hydrocele is tapped, it is of course wounded, and then the fluid which is discharged is deeply tinged with blood. Should the bleeding continue after the evacuation of the hydrocele, the blood will accumulate in the cavity of the tunica vaginalis, and in the course of two or three hours the scrotum will again be considerably swollen. In one or two examples, I have known hæmatocele follow the tapping of a hydrocele with a lancet or other sharp-edged instrument. Sir Astley Cooper has noticed this risk as attending the plan of tapping a hydrocele with a lancet. (*On the Structure and Dis. of the Testis*, p. 212.) A gentleman in the Fleet prison took it into his head to tap his hydrocele with a kind of long spring-lancet of his own invention: the operation was followed by the rapid formation of a very large hæmatocele.

Sometimes one of the enlarged veins of the tunica vaginalis bursts of itself, after the fluid of a hydrocele has been discharged, and hæmatocele then comes on, as it were, spontaneously. According to Sir Benjamin Brodie, hæmatocele may arise from a diseased condition of the arteries. "This is analogous to that which occurs in the brain under the form of sanguineous apoplexy. There is a natural change which takes place in the arteries of old persons; they become ossified in patches and ulcerate; and I have known this to lay the foundation of hæmatocele." (See *London Med. Gaz.*, vol. 1831–32, p. 927.)

As Sir Astley Cooper observes, hæmatocele is often connected with hydrocele, and a consequence of it. The latter disease frequently becomes complicated with hydrocele from an accidental blow on the tumour, occasioning a rent in the tunica vaginalis. In one case, operated upon by Sir Astley Cooper, this membrane had been ruptured to the extent of between one and two inches. The same distinguished surgeon records the case of a gentleman, in whom hæmatocele arose, not from a blow, but from excessive bodily exertion. (*On the Structure, &c., of the Testis*, p. 213–215.)

However, of all the causes of hæmatocele, a blow on the scrotum is the most frequent, and especially a blow from the pummel of the saddle in riding. I have known the disease produced, however, by external violence of different kinds; as by a fall against a piece of timber, by which the scrotum was violently struck. After such accidents, the scrotum will suddenly swell to double or treble its natural size. Every swelling so produced in the scrotum by effused blood is not invariably a collection of this fluid in the tunica vaginalis, for sometimes the extravasation is in the loose cellular tissue external to this membrane. Hæmatocele is to be distinguished from the latter case partly by the oblong or pyriform shape of the tumour, its obscure fluctuation, its freedom from the common appearances of ecchymosis, and its presenting itself more on one side of the scrotum than the other; while an extravasation of blood in the cellular tissue generally is more diffused, produces a dark blue discoloration of the part, and conceals more or less both testes.

When hæmatocele occurs in combination with hydrocele, the blood is mixed with the serous fluid contained in the tunica vaginalis, and partially dissolved in it: if the quantity of blood be small, the solution is complete; but in the opposite case coagula are formed, which remain undissolved. (*Sir B. Brodie, ib.*)

In the dissection of some hæmatoceles, the tunica vaginalis is found excessively thickened; and the blood in it, whether coagulated or fluid, is of the colour of coffee. Sir Astley Cooper refers to a preparation at St. Thomas's Hospital, exemplifying the serious mistake of removing the testicle, while the true disease was merely hæmatocele. The tunica vaginalis was excessively thickened, and filled with coagulated blood of a brownish red colour. (*Op.* cit., p. 215.)

A negro died in St. George's Hospital who had an enlargement of one testicle; but, as it had occasioned little or no inconvenience, the surgeon had not been consulted. Sir Benjamin Brodie examined the part after the patient's death, and found a very large quantity of grumous blood in the tunica vaginalis, and at the back part a soft, pulpy mass was seen, not at all resembling the testicle in structure, and only recognisable as such by its connexion with the epididymis and vas deferens. Sir Benjamin Brodie conceives that the changed state of the testicle had been occasioned by the pressure of a large quantity of blood. (See *Lond. Med. Gaz.*, 1831–32, p. 927.)

Hæmatocele is sometimes unaccompanied by pain: this is the case when the quantity of blood is small, and no inflammation present. Under other circumstances, the disease may be attended with excessive pain, and bring on abscesses, gangrene, and dangerous degrees of constitutional disturbance. This was exemplified in the person whom I have mentioned as having produced hæmatocele by plunging a large lancet into his own hydrocele, for the purpose of curing it himself. In this instance, which I visited with Mr. Bransby Cooper, if a free and prompt incision had not been made to discharge the matter and putrid blood, the patient would soon have lost his life by the violence of the constitutional disturbance. Sir Benjamin Brodie mentions a painter, who was in the habit of drinking to excess, and who, while climbing a ladder, was seized with pain in the testicle, and an enormous hæmatocele formed. In this patient the symptoms at first were more nearly allied to mania than delirium.

If hæmatocele be occasioned by a blow, and not accompanied by hydrocele, and the quantity of blood in the tunica vaginalis be moderate, the treatment should consist in keeping the patient in the recumbent position, applying leeches, administering purgative medicines, and covering the tumour with a cold lotion, which will have the effect of checking any farther internal bleeding. These means will prevent inflammation, and, after a time, the blood will probably be absorbed. Were the quantity of blood considerable, its pressure might cause an absorption of the testicle (Sir B. Brodie), or, at all events, it would be likely to excite inflammation, and have little or no chance of being dispersed: in such a case, therefore, the best practitioners agree respecting the propriety of laying open the tunica vaginalis and taking out the blood.

If hæmatocele be combined with hydrocele, and free from much inflammation, Sir Astley Cooper recommends making an incision into the tunica vaginalis, discharging its contents, and, without introducing any lint into the cavity, leaving the cure to be completed by the process of inflammation. (*On the Structure, &c., of the Testis*, p. 216.)

If, on drawing off a hydrocele, the contents are tinged with blood, Sir Benjamin Brodie allows the fluid to collect again, and repeats the tappings at intervals until no blood is mixed with it. The injection may then be used with success. Should the quantity of blood be large, he regards the expectation of its being removed by absorption as hopeless, and therefore punctures the tunica vaginalis with a lancet, introduces a director into the opening, and then enlarges it with a scalpel. (*Ib.*)

Whoever has read the observations of Pott on this subject will know that the operation of laying open the tunica vaginalis for the cure of hæmatocele is sometimes followed by a severe attack of symptomatic fever, delirium, and even death. In unfavourable constitutions, the symptoms will generally prove serious, whatever be the mode adopted in dressing the wound or the internal treatment. But now that the plan of introducing lint and other extraneous substances into the exposed cavity is abandoned, bad cases are far less frequent than formerly. The violence of the symptoms will generally depend upon the degree of inflammation in the parts, and the kind of constitution in which it occurs. If hæmatocele excite inflammation, the clots of blood putrefy, and a gangrenous suppuration follows, attended with an accumulation of sulphuretted hydrogen in the part, and most urgent danger. Here a free opening must be made without delay, the scrotum poulticed or covered with cold lotions, and the patient kept under the influence of the muriate or acetate of morphine.

Mr. Pott, in his account of hæmatocele, comprehends one species, which he describes as an extravasation of blood within the tunica albuginea.

I confess that no good reason appears for arranging cases of this kind with hæmatocele; for what are they but diseased testicles which have been punctured, either on account of their seeming to contain a fluid, or really having within them cysts filled with chocolate-coloured or other fluid, as I have seen in hundreds of instances of sarcocele? and, whatever blood is discharged, is not extravasated in the substance of the testis previously to the puncture, but issues as a necessary consequence of that proceeding.

Another species of hæmatocele, noticed by Pott, "arises from a bursting of a branch of the spermatic vein, between the groin and scrotum, within the sheath of the cord. This, which is generally produced by great or sudden exertions of strength, feats of agility, &c., may happen to persons in the best health."

I cannot conceive that, in any case of a mere rupture of one of the spermatic veins, it can ever be justifiable to tie the whole spermatic cord, and then perform castration, though Pott advises this plan, if the bleeding branch cannot be tied singly. Discutient applications and an occasional purge will almost always disperse the swelling; and if not, opening it, and taking out the blood, applying cold, or, if necessary, filling the cavity with lint, and using compression, would be, according to my humble judgment, the most judicious treatment.—C.]

[HARE-LIP. Dr. Isaac Parish reports two cases of congenital double hare-lip, with an operation, and remarks on the method of separating

the bridge of the nose in these cases. (See *Amer. Journ. for May*, 1834.)

Dr. Mott, of New-York, has had extensive experience in this operation, having performed it nearly 200 times. In simple cases he recommends that the operation be delayed two or three months. In the compound double hare-lip he operates on both sides at the same time, with one set of stitches, leaving the intermediate portion in the form of a wedge. In the complicated variety, with fissures through the bones, he recommends an early operation, and has performed t successfully in nine days after birth, though he thinks it better to wait two or three months. When performed thus early, the fissure in the bones will close in the course of a single year. Such has been his experience in more than 20 cases of this form. He has also treated compound complicated cases, having a double fissure through the bones, with complete success.

The importance of teaching the child to feed with a spoon before attempting this operation should never be lost sight of, nor should the child be permitted to nurse after the operation until the lip is sound. Dr. Mott has never employed pins in any form of this disease, but finds the uninterrupted suture to be adequate to every variety of hare-lip. I have lately had occasion to operate upon a young lady of 20 years of age, who in infancy had been twice operated on with the twisted suture, and in both instances the pins were torn out, and the deformity being thus increased, all hope of cure was abandoned, and she grew up, therefore, without its repetition. In this case, which was a compound double hare-lip, though it was necessary to remove so much of the lip as bore the cicatrices of the former operations, I employed only the interrupted suture and strips of adhesive plaster. The result in this adult case has been most gratifying, perfect union having taken place in four days, so that the stitches were removed, and scarcely a trace of the deformity can be discovered.

In the compound complicated variety of hare-lip we often find a projection of one side of the jaw-bone in the form of a proboscis. This should be removed, as preliminary to the operation on the soft parts, by a strong pair of scissors or the bone-nippers. Dr. Mott has occasionally found it necessary to employ the actual cautery in these cases, to arrest the hemorrhage from the bone which has followed the removal of this proboscis. In such cases it is better to defer for a few days the incisions and sutures to the lip. Dr. March, of Albany, has been very successful in removing these shocking deformities by a similar operation. He too employs interrupted sutures, nearly transfixing the lip, and introducing them nearly half an inch from the edges of the surfaces which are expected to unite.—REESE.]

[HEMORRHAGE.—TOURNIQUET.

At the present day, the means for the temporary stoppage of the flow of blood through the arteries in operations are reducible to two, viz., pressure, and, in a few instances, the preliminary application of a ligature on the trunk of the vessels expected to bleed in a dangerous degree. Pressure is made either with mechanical instruments or the hand. In amputations, M. Dupuytren rarely employed any other means but the hand of an intelligent assistant, and it was only in special cases that he had recourse to the ligature or mechanical pressure. The same rule is adopted by Mr. Liston in University College Hospital; and I sometimes dispense with the tourniquet myself. Two conditions are necessary to render pressure effectual, whether made with an instrument or the hand; the superficial situation of the artery, and its position upon a bone, or some other part sufficiently unyielding to admit of the vessel being pressed against it (See *Dupuytren, Clin. Chir.*, t. iv., p. 377.)

M. Dupuytren confirms, what every experienced operator is well aware of, namely, the fact of the flow of blood through the larger arteries admitting of being commanded by means of moderate pressure. But this must be made with precision, and perpendicularly to the surface, which serves as a point of resistance. The inclination of the surfaces of the bones on which the vessels lie should therefore be recollected. For example, that of the upper surface of the horizontal branch of the os pubis faces upward and forward, and that of the first rib upward and slightly outward. Consequently, in the groin, the pressure should be directed from above downward, and from before backward; and in the hollow, above the clavicle, from above downward, and from without inward. If the operation about to be performed is likely to be long, or the artery is large or rather deep, M. Dupuytren recommends the assistant to place the fingers of his unemployed hand over those which compress the vessel, in order to second their action, and hinder them from being fatigued. But, before beginning the operation, the surgeon is always to assure himself of the exactness of the pressure. In some regions of the body, and in thin persons, the diastole and systole of the vessel are perfectly visible, and then the stoppage of them denotes that the pressure is well made The total interruption of the pulsations, as ascertained by the touch, will leave no doubt on this point. There are some amputations in which every modification of pressure may be dispensed with, even though arteries of great size are concerned: such are cases in which the principal artery will be cut only in the final division of the parts, and in which an assistant who can be relied upon will let his fingers follow closely the knife, and seize hold of the flap containing the artery, and compress this vessel just before the section of the flap is completed. This method is practicable in amputations at the shoulder, and even in those of the hip. M. Dupuytren knew of only one case in which the preliminary ligature of the artery was absolutely necessary in amputation, viz., that in which the disorganization of parts, and of the artery in particular, is such that a definitive ligature on the surface of the stump would in all probability fail. In this circumstance he sanctions tying the arterial trunk above the point at which the amputation is to be performed. (See *Clin. Chir.*, t. iv., p. 382, 385.) I would ask, however, should this measure be preliminary, or ought it not rather to be deferred till the failure of the ligature on the face of the stump has been proved? The performance of two severe operations instead of one must never be undertaken without a positive necessity. Most of the preliminary operations on the trunks of arteries, hitherto performed for the prevention of hemorrhage during amputations, and in the removal of the upper or lower jaw, are now considered to have been unnecessary. In England, we should never amputate in parts known beforehand to be so disorganized that ligatures would have no chance of securing the vessels on the face of the stump.

In the article Amputation, many observations will be found on the advantages and disadvantages of tourniquets in that operation. M. Dupuytren sometimes employed, instead of a common tourniquet, what he terms a *compressor*, which makes pressure only on two opposite points of the limb; but, as he acknowledges, it would not be sufficient, if it were necessary, as in a case of extreme debility, to arrest the blood in all the arteries of the limb. (See *Clin. Chir.*, t. iv., p. 386.) The compressor is an old instrument, consisting of a segment of a circle of steel, and the pressure of which is regulated by a screw. It has often been tried in England for the cure of popliteal aneurism. It is an instrument which, I think, ought always to be kept ready in hospitals, where many cases present themselves, especially of secondary hemorrhage from stumps, the palmar arches, &c., where its application might be of important use. Professor Regnoli, of Pisa, in a case of aneurism, where secondary hemorrhage took place from the femoral artery, high up the limb, and where, in consequence of disease, another ligature would probably have failed, applied Dupuytren's compressor, and thus made moderate pressure on the bleeding point with complete success.

TORSION.

As even the most considerable arteries, in cases of lacerated wounds, frequently do not bleed, in consequence of the violent extension of these vessels, and the change produced in the disposition of their tunics, the idea of stopping hemorrhage by methodically twisting the end of the wounded arteries, led to trials of what is called *torsion*. The practice was first hinted at by Galen, and proposed in modern days by M. Amussat, in 1829, and about the same period, also, by MM. Velpeau and Thierry. (See *Sanson, des Hemorrhagies*, p. 157.) After having ascertained, by experiments on animals, that torsion was capable of arresting hemorrhage from the femoral, brachial, and carotid, and other arteries of magnitude, M. Amussat tried the method on the human subject in amputation, castration, and the removal of the breast. In one case he adopted it after amputation at the shoulder-joint. In none of these instances did any secondary hemorrhage arise; but union by the first intention was followed only in one of the cases referred to, viz., that of a child. In 1829, M. Lieber, surgeon to the new hospital at Berlin, tried the plan with equal success; and about the same period it was had recourse to with success by Dr. Fricke, of Hamburgh, by MM. Rust and Dieffenbach, of Berlin, and by M. Schrader, of Dresden. On the other hand, in France, the practice of torsion proved unsuccessful after two amputations performed by Professor Delpech. As the patients did not die of secondary hemorrhage, perhaps their cases have nothing to do with the advantages or disadvantages of torsion. In the hospital of St. Louis, at Paris, however, torsion failed in five out of six cases of amputation. Baron Dupuytren, having been requested by the Institute to make a report of the merits of the plan, tried it in the Hôtel Dieu, and came to the conclusion that *torsion may be safely applied to arteries of small calibre, but that it is imprudent to trust to it when they are of a large size.* (See *Clin. Chir.*, t. iv., p. 410.) In a certain number of instances, torsion of the arteries has been followed by extensive inflammation and abscesses in the sheath of the artery.

With regard to its increasing the chance of union by the first, inasmuch as no extraneous substance is left in the wound, experience has not proved that it has any advantage over the ligature (*Dupuytren*, vol. cit., p. 411); and, as M. Manec's researches show, the process of torsion kills a small portion of the artery, and the little slough is, in point of fact, quite as much an extraneous substance as the ligature itself. (See *Traité Théorique et Pratique de la Ligature, &c.*; also *Sanson, Op.* cit., p. 161.) Torsion is practised in two modes; in one, which is termed by the French *torsion libre*, the end of the artery is taken hold of with a pair of forceps, gently drawn out, and twisted round from four to six or eight times, according to its size. This is the plan adopted by M. Thierry (*De la Torsion des Artères*, Paris, 1829) and by Dr. Fricke; but as it has been found sometimes to produce inflammation, extending along the coats of the vessel, and even to rupture a collateral branch, the plan recommended by M. Velpeau is mostly preferred in France. This gentleman takes hold of the end of the artery with a pair of forceps, having a groove or not, draws it out of the wound, and separates it from the surrounding tissues: then he takes hold of it near its base with a second pair of forceps, with which he fixes it, while with the first pair of forceps he performs the torsion, three or four times for small arteries, and eight for large ones. (*Sur la Cessation Spontanée des Hemorrhagies, &c.*, Paris, 1830.) Some improvements were made in the practice of torsion by M. Amussat. He prefers forceps with longish, flat blades, and which admit of being kept firmly shut with a screw. He aims particularly at dividing the inner coats at the base of the end of the artery with his finger-nail, or the second pair of forceps, and then pushes them away from the surface of the wound, as it were, into the vessel. The torsion then only affects the external coat. The artery is thus closed by a kind of double valve, or, rather, barrier, viz., that formed of the internal coats, and another by the twisted external one.

In practising torsion, great care should be taken not to introduce one of the blades of the forceps into the mouth of the artery; for then all the three coats might be torn, and the bleeding not be stopped. (See *Dupuytren, Clin. Chir.*, t. iv., p. 405.)

We find, then, that torsion does not consist in merely twisting the end of the artery, but that the two internal coats are also to be separated from, and pushed back from, the external one by the manœuvres adopted. Then the torsion is of the external tunic.

As the twisted end of the artery sloughs, and necessarily excites some degree of suppuration, this fact seems to explain why torsion is not less objectionable than the ligature, as preventing union by the first intention. On the whole, I believe that M. Dupuytren's report of it, above referred to, is as correct as it is concise. The ligature only interferes with union by the first intention in the part of a wound where it lies the rest may still heal in this desirable manner.

The hemorrhage from the bites of leeches sometimes proves exceedingly obstinate, and instances of death from this cause have occasionally happened, particularly in children. When common methods fail, the plan has been recently tried of passing a fine sewing-needle through the skin on one side of the wound, and another through the skin on the opposite side, and next

twisting some thread round the needles, so as to draw them together, and close the bite. The experiment fully answered. (See *Lond. Med. Repository*, January, 1819, p. 23–26.)

Though arterial hemorrhage in operations has received full attention, it must be acknowledged, with M. Dupuytren, that venous bleeding has not attracted due consideration. At the instant of the soft parts being divided, where the course of the blood has been suspended by compression, a profuse quantity of the fluid sometimes gushes from the wound. Inexperienced surgeons, alarmed by the circumstance, stop the operation, and, by deranging the compression already made, rather increase than lessen the bleeding. Here, according to Dupuytren, *the colour of the blood should guide the operator. If dark-coloured, it comes from the limb below the incisions*, and, as it will soon cease, it is of no importance. But in operating on parts abounding in veins, and in which the circulation has not been interrupted, the dark-coloured bleeding will sometimes go on, fill the wound, and hinder the operator's proceedings. This is often illustrated in laryngotomy and tracheotomy. In other instances, the blood flows out profusely from the large veins which are divided, the patient turns pale, and seems as if he would perish on the operating table. Dupuytren observes that the continuance of such hemorrhage depends more upon the patient suspending respiration than on the size of the veins, and the blood not being then able to pass through the lungs, makes its escape from the veins divided in the operation. Here it is inexpedient to apply ligatures; because, if one set of veins were tied, another set would begin to bleed. But directly the patient has filled his lungs two or three times completely with air by making full inspirations, the hemorrhage ceases. These precepts were never forgotten by Dupuytren whenever he divided considerable veins, either in the trunk, face, neck, or upper part of the limbs. (See *Leçons Orales de Clinique Chir.*, t. iv., p. 392.) It would appear, from the researches of M. Poiseuille, that the interruption of respiration only has influence on the portion of the venous system above the diaphragm. (See *Journ. Univ. Hebdom. de Médecine*, t. i., p. 289, et t. iii., p. 97, 8vo, Paris, 1830.) However this may be, the practical observations of M. Dupuytren are highly important with reference to venous hemorrhage in the extraction of fibrous tumours from the nose, or antrum tracheotomy, and all other operations in the anterior region of the neck, a region so abundantly provided with veins of all sizes. The long and deep inspirations, however, recommended for the suppression of venous bleedings, are suspected by M. Sanson to have had, in some instances, a share in promoting the entrance of air into the veins, particularly when one of those in the upper part of the body has been wounded, and, in consequence of its parietes being indurated, it gapes, as was once exemplified to M. Delpech, in the axillary vein. (*Clin. Chir. de Montpellier.*) The passage of air into the wounded veins, observed by Beauchène, Dupuytren, Græfe, Mott, and Clemot, usually destroys the patient almost instantly, unless care be taken to place a finger over the wound in the vein, as was done by M. Clemot. (See *Sanson, des Hemorrhagies Traumatiques*, p. 91.)—C.]

[HEMORRHOIDAL TUMOURS. Dr. J. C. Warren has operated very frequently for this disease, and with extraordinary success. In 160 cases he practised complete excision by the knife, and in 35 he combined both the ligature and the knife; nor has he, in any of them, met with any bad consequences. A very large proportion of the cases were completely cured, and in all of them the patients were so benefited as not to regret the operation. In seven cases, prolapsus ani demanded the use of the knife, and in all these he succeeded without any untoward results.

Indeed, the use of the knife for the removal of hemorrhoidal tumours, as advocated in the Dictionary, is practised in the United States to a great extent. That alarming hemorrhage has occurred in the hands of surgeons, requiring the actual cautery for its suppression, will be seen by the testimony of Dupuytren, who nevertheless strenuously advocates the use of the knife.

Very many American surgeons, however, employ the ligature, variously modified, instead of the knife. Some, by passing a needle through the tumour doubly armed, and then tying the ligature on both sides, and allowing the ligature to remain until it sloughs off, which often requires several days. Many others, however, adopt the canula and wire ligature, as recommended by Dr. Physick; and Dr. Gibson has succeeded in this way in cases as formidable as those described by Dupuytren, without any of the mischiefs which followed the excision practised by that surgeon. Its advantage consists in the wire being at once permanently tightened, so as to destroy the part in a few hours, when it can be removed, instead of inflicting the protracted torture which the ordinary ligatures require for successive days and nights.

Very valuable practical hints on this topic will be found in Dr. Gross's late edition of Liston's Elements.—Reese.]

[HERNIA. In the first volume of the *Trans of the Medical and Surgical Association*, my friend, Mr. James, of Exeter, has inserted an interesting paper on the signs which distinguish the sac in hernia. Among others, not perhaps adverted to by writers, he mentions the *possibility of drawing* down more *of the intestine*. "If (says he) we have opened the sac, I believe I may affirm that it will rarely happen that we cannot draw down some farther portion—a very good practice, too, on many accounts; while, if we have not, this will be manifestly impossible.

"Another point, which has not been adverted to, is the very *size of the tumour*, which offers, as it appears to me, a highly important indication; for if it be small intestine, it must, if exceeding the dimensions of an ordinary knuckle, present the appearance of a convolution, supposing the sac has been opened; or, if great intestine, it must exhibit its characteristic appearance of bands." (P. 151.)

Dr. O'Beirne is the author of some original observations on the primary causes of strangulation, and on what he considers to be an improved mode of performing the taxis in cases of intestinal hernia. The latter consists, first, in the introduction of a gum-elastic tube into the sigmoid flexure of the colon, and retaining it there while the taxis is tried. Secondly, if this fails to diminish the size and dimensions of the hernial tumour, a syringe is attached to the tube, and emollient enemata thrown up, the same process being repeated until the bowels are sufficiently freed of their solid and fluid contents, and then the tube is again introduced without the syringe being attached to it.

Dr. O'Beirne informs us that he has employed

this treatment, and seen it employed by others, during the last eight years, with the most gratifying results. Some of the cases alluded to, with an exposition of the principles on which they were treated, appeared in February, 1833, in his work entitled *New Views of the Process of Defecation, &c.*, and others were afterward recorded in the *Lond. Med. and Surgical Journal.* It is Dr. O'Beirne's doctrine, that the abdominal openings are perfectly inactive in the production of strangulation, and that the causes of this state exist in the protruded parts themselves. He argues that, when the protrusion takes place, a current of flatus is impelled into the protruded intestine, "which becomes so distended as to be driven (the sac alone being interposed) against the firm margins of the ring, and often with such force as considerably to dilate the latter. The distention is of course resisted by the ring, and, according to the situation of the hernia, either by a strong or a weak fascia; but below this point, the bowel being opposed by little more than common integuments, yields readily, and becomes rapidly enlarged to a size so disproportionate to that of the opening through which it descended, that it is no longer capable of repassing into the abdomen. There is, at the same time, another cause operating to prevent its return; for the great expulsor muscles, although they soon cease to act simultaneously or with the same force, still act so as to direct and maintain a constant current and pressure of flatus against the strangulated gut. There are reasons for believing, also, that the bowel is more or less enlarged above as well as below the ring, so that the latter lies imbedded in a hollow formed by the sac and the intestine. In this way, pressure from within and resistance from without unite in causing the margins of the herniary opening, although totally inactive, *per se*, to produce a much greater degree of constriction of the sac and the intestine than they could possibly produce if they really possessed the activity attributed to them by many." Dr. O'Beirne differs from Mr. Geoghegan in believing that, when a knuckle of intestine becomes strangulated, air may still pass into and out of the bowel so constricted, in consequence of the existence of a narrow channel of communication between the protruded bowel and that within the abdomen. That this is frequently the case, I think all practical surgeons will admit; but whether it is constantly the case, seems to me questionable. Be this as it may, Dr. O'Beirne contends that the cavity of the strangulated gut is not obliterated, but permits air to pass freely into and out of it; that all the portion of the small intestines within the abdomen and the whole of the cœcum and colon are dilated, and also afford free passage to the air; and that the rectum is contracted, and alone opposes the escape of this elastic substance. If, previous to or during strangulation, the bowels should be loaded with solid and fluid feces, so as to prevent the passage of flatus, or the success of the first introduction of the tube, Dr. O'Beirne insists on the necessity of persevering, with the aid of repeated enemata. The gum-elastic tube used by him is sixteen inches in length, and the syringe about seven inches long and one in diameter. The tube should be made stiff by immersion in cold water, made straight, and then a few inches of it are to be well oiled. It is to be introduced as the patient lies on his left side, and passed up inch by inch, and in the course of the rectum. If stopped, it may be slightly withdrawn, and afterward passed gently upward. But if it cannot be got farther up without much force, the syringe is to be attached to it, and fluid thrown up in a strong, unbroken column by an assistant against the point of resistance, while the surgeon urges the tube firmly upward. Many other interesting observations on this practice have been inserted by Dr. O'Beirne in the *Dublin Journ. of Med. Science*, vol. xiv., art. 7.—C.]

[The late Dr. Joseph Parish, of Philadelphia, a short time before his death, published a volume of "Practical Observations on Strangulated Hernia, and some of the Diseases of the Urinary Organs." In this work the student of surgery will find a greater amount of practical information on this subject than can anywhere else be obtained in our language. The same surgeon has also published in the Eclectic Repertory, vol. i., p. 98, a case of strangulated hernia, with observations on the treatment of mortified omentum.

In the American Journal for 1840, Dr. Eve reports two interesting cases of hernia, in one of which the patient has entirely recovered after the cœcum was removed.

Dr. N. R. Smith, of Baltimore, has operated for strangulated hernia in forty-one cases, and the result of his operations has been the entire recovery of the patient in thirty-three instances. Dr. Mussey, of Cincinnati, has lost three only out of twenty-four operations for strangulated hernia, and gangrene had preceded the operation in two of these.

Dr. Pancoast, of Philadelphia, has devised and executed an ingenious operation for the radical cure of reducible hernia, by the injection of the sac after its contents were returned, and a truss applied over the internal ring, so as to shut off the abdominal cavity. He employed for the purpose a gold tube or canula, sheathed upon a large acupuncture needle, the tube being thin and closely fitting the needle, so as to enter the sac without difficulty. The needle being withdrawn, with a small syringe he injected thirty minims of the tinc. canthar. in some cases, and the tinct. iodine in others, into the sac. A compress and strong truss being then applied, the patient was confined to bed for a fortnight. When the sac was small, he found a single operation sufficed to prevent the descent of the hernia, but when it was of larger size, the injection was repeated two or three times. Ten cases were thus treated at the Philadelphia Hospital, and no peritoneal inflammation or other untoward result followed. These patients were thus relieved from wearing a truss, and for months afterward, while they remained under observation, had no return of the hernia.

Dr. Detmold, of New York, has lately performed the same operation as for strangulated hernia in a case of reducible hernia, and effected a radical cure. He was induced to attempt it at the importunity of a lady, who was abandoned by her husband immediately after marriage, on discovering the hernial tumour under which she had long laboured, but of which he had not been informed. He regarded the concealment of the defect as releasing him from his nuptial contract, and she therefore applied to Dr. Detmold and besought him to perform the operation, declaring that, unless this obstacle to her union could be removed, she would drown herself. The nature of the infirmity was fully explained to the husband, but his prejudices resisted every remonstrance. Under these circumstances, Dr. Detmold proceeded with the operation as in cases

of strangulation, and, having cut down upon the sac, he reduced it without opening it, scarified the annulus and filled it with lint, producing granulation and closure of the sacculus, effecting a complete cure of the hernia. When the recreant husband heard of the devotion of his wife, manifested in submitting to this painful and hazardous operation, he relented, and without waiting for the result, received her as his wife, and the parties are ever since happily united, surgery having removed the only hinderance to domestic felicity.

M. Guerin, of Paris, has recently applied the subcutaneous method to the operation for strangulated hernia. The only case yet reported in the Gazette Medicale was a congenital epiplocele, which had been strangulated three days. The division of both the abdominal rings, and of the antero-superior wall of the inguinal canal, was effected subcutaneously, and the reduction was immediately accomplished. If this surgeon continues to prove the success of this method of operating, vision will soon cease to be necessary among the qualifications for a surgeon, for a blind man could perform subcutaneous operations as well as M. Guerin himself, since a knowledge of anatomy with the sense of touch are the only requisitions in such operations.

Complicated cases of hernia, in which a finger-like protrusion or duplicature of the peritoneum was found covering the sac, so as to present the appearance of a hernial sac anterior to the true hernia, and rendering diagnosis difficult until, on opening it in the operation, the parts within were found to be unlike either intestine or omentum, and the true sac had to be subsequently opened, and both to be returned into the abdomen. Professors McClintock and McClellan, of Philadelphia, have encountered these cases.

The various measures proposed for the radical cure of hernia have attracted much attention in the United States within the last ten years, and several contrivances of the nature of trusses have been introduced to the public as possessing the power of accomplishing this result with considerable certainty. The alleged radical cure of hernia in the person of a farmer in Kentucky, by the substitution of a rough chip of wood for the pad of his instrument, which had been worn out and could not be immediately replaced, led to the construction of several instruments by Dr. Hood of that state, which were said to prove successful in most cases, by causing obliteration of the neck of the sac and its agglutination to the surrounding parts by adhesive inflammation.

These instruments, which had been introduced by the agents of the inventor to the notice of the French and English surgeons, have not maintained their position in professional confidence after undergoing the test of experience; but in the investigations induced by their publication originated a series of inventions by Dr. Heber Chase, of Philadelphia, which have received the sanction of many of the most prominent surgeons. In the year 1834, the whole subject of the radical cure of hernia by means of trusses was referred by the Philadelphia Medical Society to a special committee of three surgeons, and, after three years' careful observation, they produced a report highly favourable to the claims of the inventions of Dr. Chase. Their opinions and cases will be found in a preliminary report published in the *American Journal of Medical Sciences* for February, 1836, and a final report in the same journal, for August, 1837. The views of the inventor are

fully developed in a work entitled "Treatise on the Radical Cure of Hernia by Instruments, by Heber Chase, M.D., Philadelphia, 1836," which contained, also, an extended analysis of the *modus operandi* of all the variety of the truss.

The chairman of the committee of the Medical Society, Dr. Reynell Coates, considering the theory of cure by agglutination as erroneous, and attributing the unsuccessful results of the instruments of Dr. Hood, and the failure of some of the earlier attempts of Dr. Chase, to the modifications of the form of the pads employed, avowedly with the view of producing irritation and consequent adhesion, strongly urged the opinion that the occasional success attendant upon the use of ordinary trusses, and the happier results of some of the novel contrivances, were due, not to adhesion, but to a coarctation of the hernial orifice, similar to that occurring in the lower portion of intestine in artificial anus, and in other false passages under certain circumstances. His views are presented in an elaborate letter, found in Chase on Hernia, p. 107, and led to the abandonment of the attempt to produce irritation intentionally.

From this period the efforts of Dr. Chase were directed exclusively to the perfection of the means for producing complete and permanent retention of the bowels, and their success may be judged by the few extracts appended to the following enumeration of the essential and novel portions of the several apparatus.

The most important point in each of the instruments of Dr. Chase is the pad or block, because upon this depends most absolutely the retentive power. To be fully understood, each block, or a plan and perspective view of it, must be seen; but the following verbal description will give some idea of their appearance. They are all formed of some smooth wood, not too hard or too porous.

For common *inguinal hernia*, the block resembles a longitudinal section of a long oval spheroid, generated by the revolution of the curve upon its axis, and afterward moulded by force, producing considerable flattening upon one side, and a much more abrupt curvature upon the other. The long axis of the block is designed to make pressure from a point half an inch or more outward, and upward from the internal abdominal ring to near the middle of the external ring. The thicker, or more abruptly curved side, forming a very slightly prominent shoulder, compresses accurately the whole length of the abdominal canal, and the thinner, broader, and more compressed side gently but firmly supports the neighbouring parts of the abdominal surface, and, with them, the circumference of the hernial orifice, be it large or small.

For *ventro-inguinal hernia*, the block resembles that for common inguinal hernia, the spheroid being much broader, if we suppose it to be very strongly compressed upon its upper or broader convexity, until its lower or more sudden curvature is made to overhang the base to a great extent, particularly near the middle of the length of the block; so that when the block is placed upon its base and viewed perpendicularly, it presents on one margin a semi-elliptical curvature, and on the other a very effuse parabola. The compression of the spheroidal segment is much greater towards one extremity than at the other, so that the substance of the block is made to overhang the base very far at the opposite end; and hence the thickest part, as well as the most

overhanging portion, is found at about two thirds of the entire length distant from the thinner extremity. The most projecting part of the overhanging edge, when applied, corresponds with the edge of the pubic bone exactly at the base of the external ring, but it is prevented from pressing upon the bone by its curvature. The thinner end of the block extends upward and outward nearly to the external ring, and the flatter portion of the curved surface supports the overhanging portions of the lower belly.

The block for *femoral hernia* resembles an ovoid about two and a half inches long by one inch wide, truncated by a plane passing from the extremity of the long diameter at the narrow end, making with it an angle of about twenty degrees, to a point distant about two thirds the length of the egg. This figure is considerably flattened on either side of the plane of section, and the overhanging larger end of the ovoid is compressed until it is converted into a broad shoulder parallel with the plane of section, and running the entire width of the ovoid. When applied, this shoulder presses at first immediately beneath Poupart's ligament; and after the absorption of the subcutaneous fat, which always occurs during the use of these instruments, it is made to dip beneath the ligament, and rise towards the hernial orifice, while the remainder of the ovoidal surface compresses the inguinal canal, and extends so as to cover the cribiform fascia at the lesser extremity of the block.

These several forms of block are each surmounted by a metallic rider, and are attached to a little steel plate appended to the truss-spring by means of two screws, which pass through a fenestra in the plate, and admit of a variation of adjustment to the extent of about an inch in the direction of the longitude of the block.

The inguinal and ventro-inguinal trusses have the steel plate attached to the truss-spring by means of a short, soft iron neck, which, by its flexibility, admits of an extensive adjustment in the direction of the block. In addition to these arrangements, the femoral truss has its soft iron neck elongated, bent at a right angle, and connected with the spring by means of screws passing through a large fenestra in the spring itself, and permitting extensive and accurate adjustment in a direction from or towards the mesial line.

A plan of adjustment analogous to that last mentioned constitutes the principal peculiarity in the umbilical truss, the spring of which always encircles at least two thirds of the body.

The double truss, a novel and beautiful arrangement, consists of two single trusses, which may be respectively adapted to any combinations of hernia in the inguinal or femoral region. The springs ride over each other behind, the two spring-covers extending but two thirds of the length of the springs from their anterior extremities, where they terminate, each in a strap, one of which passing through an eyelet-hole formed by the base of the other at its place of attachment to the spring-cover, gives the double spring all the appearance of a single instrument, with infinitely happier means of adjustment.

As success depends upon the accuracy of retention, a considerable number of blocks of each kind, with slight modifications of relative proportions, are required in practice.

In speaking of these instruments, the committee of the Philadelphia Medical Society remark: "They have effected the permanent and accurate retention of the intestines in every case of hernia that has come under their observation, without inconvenience to the patient, and often under trials more severe than are usually ventured on by those who wear other trusses; trials which would be imprudent with any other apparatus known to the committee. * * *

"The committee feel justified in recommending in strong terms the instruments of Dr. Chase to the confidence of the profession, as the best known means of mechanical retention in all varieties of hernia, and as furnishing the highest chances of radical cure.

"In their preliminary report, the committee expressed decided opposition to the employment of trusses in infants. Candour demands the avowal, that farther observation has shaken their opinion on this subject. Several cases, treated at a very early age by the instruments under notice, have proved that they are borne without inconvenience in infancy. Some instances in proof of this will be found noted among the evidence in the appendix to this report. The adaptation of the trusses to the comfort of children under three years of age, and their superior certainty of action, establish their claim to preference over any other mode of treatment. Their applicability within the year has been successfully tested in two cases; and it is certain that more force is required to confine the bowels by any form of bandage or compress, than by means of a well-regulated spring and block. The only comparative trial of the soft pad and hard block on an infant has resulted in favour of the latter; but the committee feel bound to urge the necessity of high surgical skill and extremely careful attention in dealing with these little subjects.

"The time required for the radical cure of an ordinary case of ventro-inguinal or direct hernia in the adult appears to be from twelve to eighteen months. It is probable that the bowel, in common inguinal hernia, is rendered secure in a shorter time; but prudence has prevented the earlier relinquishment of the truss, except in a very few cases. The orifice in umbilical hernia appears to contract somewhat more slowly, but all the varieties recover much more rapidly in childhood.

"The cases observed include all the usual forms of external hernia, whether resulting from mechanical or physiological causes, and also some instances of double and triple hernia. The complications which have not been presented are known to be very rare, and the committee therefore feel no hesitation in expressing a strong, and, they think, well-grounded hope that a very large majority of the cases of this dreaded disease will yield to the action of the apparatus of Dr. Chase, when under the direction of persons of high surgical and mechanical abilities."—*Final Report.*—REESE.]

[HERNIA CEREBRI. Dr. G. Buck, of New York, has published, in the N. Y. Journal for 1839, an elaborate paper on this subject, to which my limits will allow me only to refer. It is creditable to the author's industry and talent.

In a case of fungus cerebri, lately treated by Dr. March, of Albany, and which occurred after a comminuted fracture of the cranium by the kick of a horse, the patient recovered after the removal of the fungus by the scalpel, under a suitable compress and adhesive plasters. The difficulties, however, often encountered in these cases has led Dr. March to suggest the application of the autoplastic method to such cases, by transfer

ring a portion of the adjacent scalp, after having prepared the edges surrounding the fungus for its reception, and the removal of the cerebral hernia. There can be little doubt of the adhesion being readily secured in such a case, and the necessary compression might thus be gained in a mode every way preferable to the means usually employed for the purpose. It is a novel application of this autoplastic principle, the suggestion of which is creditable to this surgeon, and could hardly fail of success.—Reese.]

[HIP-JOINT. Dr. John C. Warren, of Boston, has published an elaborate letter on the subject of dislocation of the hip-joint, accompanied by plates, which are well executed, and constituting together a volume of great value to surgeons and juridical practitioners. The occasion of the publication was a litigation, in which a respectable surgeon of New-England was involved by a suit for mal-practice, and in which Dr. Warren's testimony had been perverted in the style which is characteristic of a certain class of legal practitioners, who arrogate a fictitious pretension to critical knowledge in forensic medicine. Dr. Warren has treated the party concerned as he deserves, while he has accomplished his self-vindication in a manner most honourable to the profession.

Dr. George W. Norris has published, in the 25th volume of the Amer. Journal, a critical paper on the diagnosis of injuries of the hip, which is worthy the attention of the surgeon.

In Dr. Norris's American edition of Liston, p. 152, a description is given of Dr. Physick's method of treating this disease, and in which he had extraordinary success.

Professor Trowbridge reports numerous instances of recovery from morbus coxarius, or hip-joint disease, by an operation which is said to succeed after morbid results have followed the inflammation of the joint. He makes an incision between the gluteus maximus and medius muscles, and carries it down to the bone, laying open the joint. Immediately after this operation, he states, as the result of his experience, that the pain, distention, and progress of morbid action in the joint all cease, and the patient speedily recovers, in some instances entirely. He has thus opened the joint in all stages during the acute inflammation, and even after the bone has become carious; and though, in the latter cases, where the tissues of the joint have seriously suffered, some inability to use the limb may remain, yet in all instances there is a mitigation of the disease and early recovery. I have no experience in this mode of treatment, but from the failure of all other methods pursued in this formidable disease, even the actual cautery, I regard the suggestion of any method which promises better success worthy of record, and hence give place to the testimony of Dr. Trowbridge, who speaks very confidently of the safety and utility of his method.

A surgeon of Philadelphia has lately amputated at the joint for this disease: a most unsurgical and unjustifiable proceeding, and one which no reputable member of the profession will ever imitate.—Reese.]

[HYDRIODATE OF POTASSA. Frequently employed externally, in conjunction with lard, for promoting the absorption of collections of fluid, and scrofulous and other indolent swellings. The hydriodate "aids the solution of iodine in water, and on this account it is given in combination with iodine in aqueous fluids. M. Lugol's formula is of iodine gr. j½, hydriodate of potassa gr. ijss., and distilled water f℥ viij. One fourth part of this solution is to be administered in divided doses in the course of the day. M. Lugol forms a bath also of iodine by similar means." (See *A. T. Thomson's Elem. of Materia Med.*, p. 853, ed. 2.) I have known the hydriodate of potassa, given internally in doses gradually increased up to 10 or 15 grains thrice a day, disperse ascites. Frictions with the ointment over the abdomen were simultaneously resorted to. But of all the uses of the hydriodate, its efficacy in syphilis appears the most important in practice. (See Scrofula and Venereal Disease.)—C.]

[HYDROCELE. Dr. Pancoast, of Philadelphia, employs a new mode of operating upon children for hydrocele, by making an incision with a common lancet, and after a little fluid escapes, he makes pressure upon the tumour until a little bag of the serous membrane constituting the sac protrudes. This he draws out with the forceps or hook, and by alternately snipping with the scissors and gentle traction, he removes the greater part of the parietal serous tunic. He then surrounds that side of the scrotum, including its testis, with strips of adhesive plaster, and a cure has speedily followed. (See *Dunglison's Journal for July*, 1842.)

Dr. March, of Albany, after trying the various methods of operation for the radical cure of hydrocele, has for the last ten years adopted the following plan with uniform success. Holding the tumour in one hand, and making the skin tense, he makes an incision with the scalpel an inch and a half in length through the skin and cellular tissue down to the tunic, selecting its anterior and lower part. He next makes an incision one third less in extent through the tunic, and, after emptying the sac, guides the point of the syringe by his finger, and injects an ounce of tinc. iodine, previously diluted with eight ounces of lime-water. He deems this mode of incision expedient to avoid the accident which has sometimes occurred, of injecting the cellular tissue of the scrotum, and the disastrous consequences of such a blunder.

There are cases in which this course may be preferable; but, after extensive experience in this operation, by the cautious use of the trocar and canula, I have invariably avoided the accident deprecated; nor have I ever met with any impediment either to the injection of the sac, or the ready escape of the fluid employed. No one operation, however, should be indiscriminately adopted or exclusively preferred.

Dr. J. Watson, surgeon to the N. Y. Hospital, has for several years relied upon compression for the radical cure of this disease, in preference to injections, setons, or the other various methods pursued by different surgeons, after emptying the sac either by the trocar or the lancet. He straps the scrotum firmly over the testicle by means of strips of adhesive plaster, and tightens the straps as the tumour diminishes under the pressure, keeping up the compression for weeks, if required. He has found it necessary to repeat the operation in some cases a second time, and occasionally a third puncture has been necessary, but more frequently a single operation, followed by the pressure, has sufficed for the cure. An opportunity having occurred for a post mortem examination of a patient who died eighteen months after the operation, Dr. Watson found the testis sound, and no trace of disease in the tunica vaginalis. From the fact that this patient had

laboured under an extensive complication of disease in the scrotum, testis, and cord, coexisting for a long time with the hydrocele, simulating carcinomatous induration, it would appear probable that compression on the plan of Dr. Watson may be found useful in the treatment of other affections of the testis and scrotum, and deserves a trial.

This mode of compression by narrow strips of adhesive plaster has been long employed in the Pennsylvania Hospital, in chronic inflammations and enlargement of the testicle. (See *Dr. Norris's edition of Liston*, p. 447.)—REESE.]

[HYDROCEPHALUS. Professor Dugas, of Georgia, reports, in the Southern Medical and Surgical Journal for 1836, a case of chronic hydrocephalus treated by repeated paracentesis, which possesses many points of interest; for, though unsuccessful in the end, yet it proves the practicability and harmlessness of puncturing the brain in such cases, for in this case the brain was punctured seven times, and sixty-three ounces of fluid drawn off during the few months that the child survived the disease. Not the slightest unpleasant effect followed either operation; and on the autopsic examination, sixty-four ounces of a limpid fluid were found in the head, and contained in a sac composed of the expanded cerebrum lining the dura mater, and in which the cicatrices of the seven punctures were distinctly visible.—REESE.]

[HYPERTROPHY (from ὑπὲρ and τροφὴ, signifying an excess of nutrition). This term ought to be restricted to cases in which a part, though increased in bulk, retains its natural organization and structure. It is one of the most common effects of increased activity in the nutrition of textures and organs, and likewise one which may give rise to the most diversified functional disturbance. It cannot always, however, be regarded as a disease. The mere increase of size of a part, unattended with change of structure, or the interruption or disorder of any function by such hypertrophy, cannot be considered as a morbid affection. Thus hypertrophy in a muscle of animal life is not a disease, but in the heart it becomes one of the most serious. (See *Andral, Anat. Pathol.*, t. i., p. 166.) It can hardly come under the denomination of a disease until it interferes with the regular and complete accomplishment of a function. As one of the most distinguished of modern pathologists observes, "That the increased abnormal development of an organ or tissue, denominated hypertrophy, depends essentially on an excess of the nutritive function, appears to be sufficiently demonstrated by the presence, on the one hand, of an increase of bulk, and the absence, on the other, of any adventitious solid or fluid substance. The organization and structure remaining unaltered, is also farther evidence that the increase of bulk is owing to a superabundant deposition of the natural solid constituents of the affected organ from an excess of the nutritive function." (See *R. Carswell's Illustrations of the Elementary Forms of Disease*, fasciculus ix.)

1. Many hypertrophies seem to arise altogether from augmentation in the habitual activity of the functions of organs. "The prodigious development and power of the muscles of the superior extremities of the blacksmith, and of the inferior extremities of the stage-dancer, are striking examples of hypertrophy occurring under the influence of the frequent and increased exercise of a function, the effect of which is a corresponding increase of nutrition, and of development of the muscular tissue. The abnormal development of the muscles of involuntary motion, as those of the heart, bladder, and intestines, is likewise often precisely of a similar nature, an increased exercise of the muscular power of these organs having been excited and kept up to overcome a mechanical obstacle to the free passage of their respective contents." (*Carswell, Ib.*)

2. Some hypertrophies take place as the unequivocal result of what Andral calls active *hyperemia*, either acute or chronic, or, in other words, of a great determination, or of a copious afflux of blood to parts for a greater or lesser time.

3. Others proceed from some physiological or pathological stimulus, some irritation of the nutritive function creating an excess of it. (See *Andral, Précis. d'Anat. Pathol.*, t. i., p. 182.)—C.]

[HYPOSPADIAS or HYPOSPADIÆOS (from ἀπο, under, and σπαω, to draw). The congenital imperfection in which the urethra terminates at the under part of the penis, and does not extend sufficiently far forward to reach the right situation of its orifice in the glans. Sometimes there is a vestige of this orifice, sometimes none. Half an inch or more of the urethra may be deficient. About two years ago I was consulted by Mr. Baker, of Staines, for a case of hypospadias in a young child. In this instance I cut a new passage through the glans, and, having established a communication between it and the urethra, introduced a silver tube. This was worn for some time, and the little opening having been touched with caustic, a complete cure was brought about. The management of the case was attended with some difficulty, and would not have answered with a piece of elastic gum catheter, which was at first tried; and it was necessary to get Messrs. Weiss to fabricate, at a short notice, a silver tube for the purpose, furnished with a rim, and apertures by which it could be conveniently fixed. Mr. Liston has sometimes succeeded in completing the passage by turning back a portion of the prepuce, and uniting it without any twist, *i. e.*, with the lining membrane outward. (*On Practical Surgery*, p 476.)—C.]

J.

[JAW-BONE. Dr. J. C. Warren, of Boston, has twice amputated the upper jaw; in his first case the patient died three months after by the return of the disease, osteosarcoma; but in the other case, complete success crowned the operation. The same surgeon has removed large portions of the lower jaw seven times with astonishing results, all his patients having recovered.

Dr. Valentine Mott, of New-York, has performed the exsection of portions of the lower jaw ten times; and in two instances he has removed this bone at the articulation on one side. In one of these latter cases, the tumour, osteosarcoma,

was nearly as large as the patient's head; and involving the symphysis, as it did, the bicuspid tooth of the opposite side was removed, and the bone sawed through at that point, while on the other side it was necessary to remove it at the articulation.

For Dr. Mott's operation for removing immobility of the lower jaw, see note on article Anchylosis in the text of this edition.

Dr. Mott has removed portions of the upper jaw fifteen times.

Professor Alexander H. Stevens, of New-York, reports a case of osteosarcoma of the upper jaw, successfully treated by the extirpation of the whole of the superior maxillary and malar bones, and portions of the œthmoid and sphenoid bones. The account of this formidable operation, with remarks alike creditable to the author's science and humanity, will be found in the N. Y. Journ. of Med. and Surg. for 1840. In the article Antrum, it will be seen that Dr. Stevens was the first surgeon who ever removed the upper jaw. His operation was in 1823, and Dr. David L. Rogers's case in 1824, both of them prior to Mr. Lizars's, of Edinburgh, to whom Mr. Liston attributes this merit by mistake.

Dr. Paul F. Eve, of Augusta, Georgia, has twice removed the upper jaw, and once a large portion of the lower jaw by excision. The latter operation and one of the former were successful. One of the cases in which the upper jaw was removed was cephaloma, which soon after returned, and carried off the patient.

Dr. M'Clellan has removed the upper jaw thirteen times, and has performed numerous operations on the lower jaw, removing portions of this bone nine times—twice more than half the bone, including the articulation on one side, and in one instance excising the whole of the lower jaw.

Dr. N. R. Smith, of Baltimore, has successfully amputated the lower jaw; and in one case he removed all that portion between the second molar of one side and the condyle of the other.

Dr. F. D. Mutter, of Philadelphia, has removed nearly the whole of the upper jaw, including both superior maxillary bones, which were involved in that malignant form of disease called epulis, and which originated in the gums. The difficulty has been since remedied by the introduction of a gold plate, to which a row of artificial teeth has been attached, and which conceals the deformity. Dr. Mutter has twice removed a large portion of the lower jaw for osteosarcoma, and there has been no return of the disease in either case, although in one of them three years has elapsed, and the other nearly one year since the operation.

Dr. Randolph, of Philadelphia, has removed nearly the whole of the lower jaw for an osteosarcomatous tumour, and the patient recovered. (See *Amer. Journ. of Med. Science for* 1829.)—Reese.]

[JOINTS, EXCISION OF. This operation consists in the removal of the parts of bones entering into the formation of a diseased joint, together with the whole of the capsular ligament and synovial membrane. "It has a twofold object: the first is to remove a formidable disease, and this might be effected by amputation; the second is to preserve a useful limb, and this amputation could not effect. The fact in morbid anatomy in which the proposal mainly rests, is, that, in the large majority of the ulcerative diseases of joints, the bone is either primarily affected, or becomes so secondarily." (See *Blackburn* in *Guy's Hospital Reports*, vol. i., p. 277.)

Whether a passage quoted by M. Velpeau from Hippocrates refers to the complete excision of joints, as sometimes practised at the present day, is doubtful. As Mr. Blackburn observes, it may only allude to the removal of the ends of bones in compound dislocations. The record of the first actual performance of the operation is to be found in a note appended by Mr. Park, of Liverpool, to a collection of pamphlets on this subject published by Dr. Jeffray, of Glasgow, in 1805. It is there stated that, in 1762, Mr. Filkin, of Northwich, in Cheshire, in a case of diseased knee, removed the patella, along with the articular extremities of the femur and tibia. A similar operation was performed on the shoulder in 1767 by M. Vigaroux, of Montpellier. (*Œuvr. de Chir. Pratique*, Montpellier, 1812. In 1769, Mr. White, of Manchester, removed the diseased head of the humerus, and with such success that the patient could afterward carry heavy weights, and regained every motion of the arm. (See *White's Cases and Obs., Phil. Trans.*, vol. lix.) In 1771, White's practice was imitated by Mr. Bent, of Newcastle, and a few years afterward by Mr. Orred, of Chester. (See *Phil. Trans.*, vols. lxiv. and lxix.) With the exception of Mr. Filkin's case, however, in all these examples only one articular surface was removed. (See Amputation.) The merit of suggesting the operation, as defined in the first sentence of this article, unquestionably belongs to Mr. Henry Park, of Liverpool. In a letter to Mr. Pott, dated 1782, Mr. Park made the proposal of totally extirpating many diseased joints, by which the limbs might be preserved, with a share of motion that would still allow them to be very useful. In order to learn whether the popliteal vessels could be avoided without much difficulty in the excision of the knee, Mr. Park made an experiment on the dead subject. An incision was made, beginning about two inches above the upper end of the patella, and extending about as far below its lower part. Another one was made across this at right angles, immediately above the patella, down to the bone, and nearly half round the limb, the leg being in an extended state. The lower angles formed by these incisions were raised, so as to lay bare the capsular ligament; the patella was then taken out; the upper angles were raised, so as fairly to denude the head of the femur, and to allow a small catling to be passed across the posterior flat part of the bone immediately above the condyles, care being taken to keep one of the flat sides of the point of the instrument quite close to the bone all the way. The catling being withdrawn, an elastic spatula was introduced in its place, to guard the soft parts while the femur was sawn. The head of the bone thus separated was carefully dissected out; the head of the tibia was then with ease, turned out and sawn off, and as much as possible of the capsular ligament dissected away, leaving only the posterior part covering the vessels, which, on examination, had been in very little danger of being wounded.

The next attempt was on the elbow: a simple longitudinal incision was made from about two inches above to the same distance below the point of the olecranon. The integuments having been raised, an attempt was made to divide the lateral ligaments and dislocate the joint; but this being found difficult, the olecranon was sawn off, after which the joint could be easily dislocated without any transverse incision, the lower extremity of the os humeri sawn off, and

afterward the heads of the radius and ulna. This appeared an easy work; but Mr. Park conceives the case will be difficult in a diseased state of the parts, and that a crucial incision would be requisite, as well as dividing the humerus above the condyles, in the way done with respect to the thigh-bone.

Mr. Park first operated, July 2, 1781, on a strong, robust sailor, aged 33, who had a diseased knee of ten years' standing. The man's sufferings were daily increasing, and his health declining. Mr. Park wished to avoid making the transverse incision, thinking that, after removing the patella, he could effect his object by the longitudinal one; but it was found that the difference between a healthy and diseased state of parts deceived him in this expectation. Hence the idea was relinquished, and the transverse incision made. The operation was finished exactly as the one on the dead subject related above. The quantity of bone removed was very little more than two inches of the femur, and rather more than one inch of the tibia. The only artery divided was one on the front of the knee, and it ceased to bleed before the operation was concluded, but the ends of the bones bled very freely. In order to keep the redundant integuments from falling inward, and the edges of the wounds in tolerable contact, a few sutures were used. The dressings were light and superficial, and the limb was put into a tin case sufficiently long to receive the whole of it, from the ankle to the insertion of the glutæus muscle.

I shall not follow Mr. Park throughout the treatment. Suffice it to remark that the case gave him a great deal of trouble, and that it was attended with many embarrassing circumstances, arising chiefly from the difficulty of keeping the limb in a fixed position, the great depth of the wound, and the abscesses and sinuses which formed. On the other hand, however, the first symptoms were not at all dangerous. But the patient was obliged to keep his bed nine or ten weeks, and it was many months before the cure was complete. The man afterward went to sea, and did his duty very well.

Subsequently to the publication of the letter to Mr. Pott, another excision of the knee was performed by Mr. Park on the 22d of June; but the event was unsuccessful, as the patient lingered till the 13th of October, and then died.

In 1783, the year following that of the publication of Mr. Park's pamphlet, the subject was brought before the Academy of Surgery in France by M. Moreau. In 1786, this surgeon excised the head of the humerus and the glenoid cavity. In 1792 he operated on the elbow, and he and his son several times excised the articular surfaces of the knee, ankle, shoulder, elbow, and wrist. Their example was followed by Sommeillier and Baron Percy. In 1809, Mülder, of Gröningen, cut out a knee-joint. (See *Wachter, Diss. de Articulis Extirpandis*, 1810.) In 1819, M. Roux, of Paris, performed the excision of the elbow. (See *Révue Méd.*, 1830.) In 1823, the same operation was executed by Mr. Crampton, who has likewise excised the knee with success (see *Dublin Hospital Reports*, vol. iv.), and in 1825 by Mr. Syme, who has excised the elbow in fourteen cases. The operation has since been repeated by these three surgeons; by Mr. Spence, of Otley, in Yorkshire; by Dr. Simpson, of Edinburgh; by one of the surgeons of the Glasgow Infirmary. (See *M'Farlane's Clin. Reports*, &c.); by Mr. C. Aston Key (see *Blackburn* in *Guy's Hospital Reports*, vol. i.), and in University College Hospital, by Mr. Liston. The operation has also been executed by MM. Champion and Mazozza. (See *Velpeau, Nouv. Elém. de Méd. Opér.*, t. i., p. 559.)

In the first elbow case, operated upon in 1782 by M. Moreau, the patient went on so favourably that he was allowed to go about wherever he pleased, with his arm supported in a case. The limb was at first powerless, but it slowly regained its strength, and the man could ultimately thrash corn with it, and hold the plough. Seven months after another operation of the same kind, performed by M. Moreau the father, the patient was completely well, and in two years more the flexion of the arm was very distinct. In another case the patient got well in six weeks, and in three months more joined his regiment.

In all Moreau's cases, the flexion and extension of the forearm were preserved, which circumstance, no doubt, depended very much on the insertion of the biceps not being destroyed. After the excision of the knee, however, the bones grew together.

Excision of the Elbow-joint.—The following is the plan of operating recommended by Mr. Syme, which is nearly the same as that practised by M. Moreau. The patient should lie with his face downward, so as to present the posterior surface of the joint. The surgeon, with a straight, narrow, sharp-pointed knife, makes a transverse incision into the joint, close above the olecranon, and extending from the inner edge of this process to the external condyle. In doing this, care must be taken to avoid the ulnar nerve, which lies close to the inner side of the olecranon; and, with this view, the safest plan is to introduce the knife perpendicularly into the joint, with its back directed towards the nerve. At each extremity of the transverse cut, the surgeon next makes an incision about an inch and a half long, both upward and downward, in the long direction of the limb, so as to form two square flaps, and give to the wound the shape of the letter H. These flaps being detached from the subjacent parts, the olecranon may be easily removed with the saw or pliers, after which no difficulty will be experienced in cutting the lateral ligaments, making the end of the humerus protrude, and sawing it off above the condyles. The head of the radius may next be cut away with pliers, and then the excision of the sigmoid cavity of the ulna, left after the removal of the olecranon, may easily be accomplished with the same instrument. "It might be thought better to take away all the ulna that required excision at once; but the attachment of the brachialis internus to the coronoid process renders this very difficult, especially if it is attempted before the free space afforded by the removal of the other bones has been obtained." (See *Syme's Principles of Surgery*, p. 214, ed. 2, 8vo, 1837; also, *Treatise on the Excision of Diseased Joints*, 8vo, Edinburgh, 1831.)

M. Moreau began the operation by making an incision, between two and three inches long, on each side of the joint, commencing about two inches above the condyles, and carried down in the direction of the ridges leading to them. These two wounds were next connected by a transverse incision through the skin and tendon of the triceps, immediately above the olecranon, and the flaps were then raised.

As soon as the flaps have been raised, Dupuytren recommends us cautiously to open the sheath of the ulnar nerve, behind the internal condyle

and the nerve to be kept inward and forward by an assistant with a bent probe, at the period when the humerus is to be divided. The preliminary removal of the olecranon, as directed by the same eminent surgeon, is regarded by M. Malgaigne as uselessly complicating the operation. (See *Manuel de Méd. Opér.*, p. 241, ed. 2.)

When the flaps have been dissected, and the ulnar nerve drawn forward in front of the inner condyle, the undivided soft parts are to be drawn in the same direction; the muscular fibres then detached from the bone with the point of the knife; a spatula or flat piece of wood introduced in front of the humerus, and the bone sawn through from behind forward. The lower piece of it is then to be inclined downward and backward, and separated from all its connexions, the anterior, external, and internal lateral and posterior ligaments being cut through in succession. As a thick muscle, the brachialis internus, is interposed between the humerus and the artery, the avoidance of the vessel is never attended with any difficulty. If it be necessary to carry the incisions down to the forearm, as far as the bifurcation of the artery, this vessel is more exposed to injury. It is of great importance, if possible, to saw the ulna above the insertion of the brachialis, and more especially the radius above that of the biceps. Mr. Syme, however, has divided the bones lower down, and yet the use of the hand was preserved. (See *Velpeau, Nouv. Elém. de Méd. Opér.*, t. i., p. 563.)

Mr. Liston prefers a single perpendicular incision at the outer side of the joint, and the transverse one. An incision is made on the radial side of the ulnar nerve, and in the direction of the limb, by pushing the point of the knife through the integuments and fibres of the triceps to the back of the humerus, and carrying it in contact with the ends of that bone and the ulna for about three inches. Another incision, commencing over the outer condyle of the humerus, and penetrating to the articulation, is made to fall on the middle of this at right angles. The two flaps are reflected, and the soft parts, with the ulnar nerve, are turned over the inner condyle. The ends of the bones, but slightly retained by their ligaments, are turned out of the wound by bending the forearm. During the cutting of the bone, the spatula is of use in protecting the nerve or other soft parts. "A partial anchylosis will be found occasionally to have formed, and then the small saw and cutting forceps may be called for. In operating upon young subjects, the cutting forceps may sometimes be used in preference to the saw, the bones being soft, and extensive removal not demanded." After bringing the edges of the wound together with three sutures, Mr. Liston applies wet lint to the wound for a few hours, and then strips of plaster; the sutures are soon removed, and the tepid-water dressing employed. After a week or two, the limb, which has been kept half bent on a pillow, is secured in splints, and supported in a sling. (See *Liston on Pract. Surgery*, p. 140.)

The elbow-joint, Mr. Blackburn observes, has been so frequently excised that it would be alike useless and tedious to present an analysis of each operation. The two Moreaus record three cases, all successful; and state that they had operated several other times, and always with fortunate results. M. Roux counts three cases which have terminated favourably, and one which terminated unfavourably. (*Révue Med.*, 1830.) Mr. Syme numbers no less than nineteen operations, of which only two have been attended with unhappy results (*On Excision of Joints, &c.*, in *Ed. Med. and Surg. Journ.* for 1832–33–4–5); and Messrs. Key, Crampton, Champion, Spence, Simpson, and one of the surgeons to the Glasgow Infirmary, can each furnish a successful case. The operation is said to have been performed with fortunate results by Mazozza in Italy, by Sommeillier in France, and by Mr. Beard, of Newcastle. Altogether there are 32 of which histories have been given. Of these, three have been fatal; one patient dying at the end of five weeks, from the combined effects of phthisis and of an enormous abscess of the hip; and the two others from accidents more immediately connected with the operation. Of the remaining twenty-nine, nearly all recovered the motion of the joint: in three or four it remained stiff and rigid, principally from neglect of the instructions given as to exercise. In no one of these cases was the constitutional irritation that followed alarming. All the patients had been suffering for many months, or for years; the most approved methods of treatment had been tried unsuccessfully, and in many instances eminent surgeons had recommended amputation. In a few, the recovery was very rapid; but in the majority, some months elapsed before the joint could be pronounced to be quite sound, as one or two small sinuses remained open, though occasioning no annoyance. The patients, in general, returned to their previous occupations. One of Moreau's was accustomed to use his arm in thrashing, ploughing, &c.; and one of Mr. Syme's wrote to him, two or three years after the operation, to say that his arm was strong enough to carry eighteen or twenty pounds' weight with ease; that he could raise six or eight pounds to his head; and that he could write and perform any ordinary work, "so that no person would know (he says) whether I had my elbow or was without it," &c. At the meeting of the British Association, held at Edinburgh in 1834, Mr. Syme produced several persons on whom the operation had been performed, along with the portions of bones removed, and Dr. Hodgkin, that the other members present were surprised and gratified by the strength and mobility which the new articulations had acquired. (*Guy's Hosp. Reports*, vol. i., p. 291–293.)

There is not, in reality, a new joint with a capsule formed, but the ends of the bones become connected by ligamentous fibres, and a sufficiently firm substance is produced to serve as a fixed point for the muscles, which execute the flexion and extension of the forearm. (See *A. Velpeau, Nouv. Elém., &c.*, t. i., p. 564.)

Besides the cases above referred to, Mr. Liston has had others which proved successful, and one of them in University College Hospital.

In general, no vessel requires a ligature. One patient, under M. Roux, however, died of secondary hemorrhage—a solitary occurrence.

Mr. Syme recommends the wound to be closed with sutures, and a long figure of 8 bandage to be applied to support the limb, "which should be bent at a right angle, and to prevent the ends of the bones from moving, or pressing injuriously on the soft parts." Rigid cases of iron or wood he deems less convenient. "The patient, after the first two or three days, will find himself most comfortable in the erect posture; and when the inflammatory tension begins to subside, he should gently, but diligently, exercise the limb, so as to preserve the mobility of the elbow." (See *Syme's Principles*, p. 215, ed. 2.)

In the five operations which Mr. Liston has performed on the adult, he has aimed at bringing about a sort of ligamentous anchylosis, by steadying the part for a long while by means of leathern splints, with the forearm at a right angle. On the contrary, in young patients, he says, "the motions of the part may be encouraged, and with every chance of their becoming free and strong." (*On Practical Surgery*, p. 138.)

Excision of the Knee-joint.—In a knee-case, Moreau, the father, operated as follows: He made a longitudinal incision on each side of the thigh, between the vasti and the flexors of the leg, down to the bone. These incisions began about two inches above the condyles of the femur, and were carried down along the sides of the joint till they reached the tibia. They were united by a transverse cut, which passed below the patella down to the bone.

The flap was raised, but the patella attached to it, being diseased, was dissected out. The limb was then bent, so as to bring the condyles of the femur into view. As it was desired to cut them from the body of the bone before dislocating them, everything adhering to them behind, where they joined the body of the bone, was separated, and at that place the forefinger of the left hand was passed through, in order to press back the flesh from the bone while the saw was used. The knee having been bent, Moreau drew the cut piece towards him, and easily detached it from the flesh and ligaments.

The head of the tibia was laid bare by an incision nearly eighteen lines long, made on the spine of that bone. The first lateral incision on the outer side of the knee was extended nearly as far down on the head of the fibula. Thus were obtained one flap, which adhered to the flesh, filling up the interosseous space, and another triangular flap formed of the skin, covering the inner surface of the tibia, which bone was of necessity exposed before the saw could be applied.

Upon raising the outer flap, the head of the fibula came into view, and, after being separated from its attachments, was cut off with a small saw. The inner flap was then raised, and the head of the tibia, having been separated from the muscle behind, was sawn off. (See *Moreau* (*le fils*), *Obs. pratiques relatives à la Resection des Articulations affectées de Carie*, Paris, an. xi.) Some cases and remarks in favour of the excision of diseased joints have been published by Mr. Crampton. (*Dublin Hospital Reports*, vol. iv., p. 185, &c.) He has removed with success one knee and one elbow. Another knee operation may be set down as a failure, no union having taken place, and a sinus and discharge having continued in the ham until the patient's death, three years and two months after the operation. Respecting the plan of operating on the knee, he concludes thus: "I am satisfied, from repeated trials on the dead subject, that the operation can be most safely and rapidly executed by separating the condyles from all their attachments previously to sawing the bone. As soon, therefore, as the flap containing the patella is turned upward, the edge of the knife should be carried round the condyles close to the bone, so as to divide *all* the ligaments which connect the femur with the tibia. The tibia can then, with great ease, be pushed backward, and as much of the projecting condyles can be removed as the operator may think necessary." (*Vol.* cit., p. 213.)

It does not appear necessary to insert in this work the account of cutting out the ankle-joint, an operation which will never be extensively adopted; nor shall I add anything more concerning the mode of removing, in a similar way, the shoulder-joint. In treating of amputation in this situation, I have already said enough, and whoever wishes for farther information respecting this practice must refer to Dr. Jeffray's work, entitled "*Cases of Excision of Carious Joints*," Glasgow, 1806. Dr. Jeffray recommended a particular, and, indeed, a very ingenious saw for facilitating the above operation. The saw alluded to is constructed with joints, like the chain of a watch, so as to allow itself to be drawn through behind a bone, by means of a crooked needle, like a thread, and to cut the bone from behind forward, without injuring the soft parts. In placing the saw under a bone, its cutting edge is to be turned away from the flesh. Handles are afterward hooked on the instrument.

According to my notions of the treatment of diseased joints, so long as the patient's strength is not subdued by the irritation of the local disease, humanity dictates the propriety of persevering in an attempt to save the affected limb, &c. Will a patient greatly reduced by hectic symptoms be able to recover from so bold and bloody an operation as the dissection of the whole of the knee-joint out of the limb? If some few should escape with life and limb preserved, would the bulk of persons treated in this manner have the same good fortune? I cannot admit that the extirpation of the whole of so large an articulation as the knee can be compared with the operation of amputation in point of simplicity and safety. However, it is not on the difficulty of practising the former that I would found my objections; for I believe that any man possessing a tolerable knowledge of the anatomy of the leg might contrive to achieve the business. The grounds on which I withhold my approbation from the attempt to cut out the knee are the following: 1. The great length of time which the healing of the wound requires. Whoever peruses the case of Hector M'Caghan will find that the operation was performed on the 2d of July, 1781, and that it was February 28th of the following year before all the subsequent abscesses and sores were perfectly healed. This space of time is very nearly eight months! Mr. Park describes the patient as a strong, robust sailor, and gives no farther particulars concerning the state of his constitution than that his health was declining. I entertain little doubt that, if the excision of the knee had been performed in that state of the health in which amputation becomes truly indispensable, this man would not have survived the illness arising from the operation. The only other case in which Mr. Park extirpated the knee ended fatally. In the instance related by Moreau, there seemed, indeed, to be considerable debility. This patient escaped the first dangers consequent to so severe an operation; and, *after three months' confinement*, the patient was in such a state that *Moreau expected he would be able to walk upon crutches in another month or six weeks!* The young man in the mean time was attacked by an epidemic dysentery, and died. On the 21st of October, 1809, Mülder extirpated the knee-joint of a pregnant woman in the hospital at Gröningen; but she died of tetanus on the 8th of the following February. He conceives that the operation is much facilitated by removing the ends of the femur and tibia in their connected state. (See

Diss. de Articulis extirpandis auctore G. H. Wachter, 1810.) 2. Even supposing the excision of the knee to be followed by all possible success, is the advantage of having a mutilated, shortened, stiff limb, in lieu of a wooden leg, sufficiently great to induce any man to submit to an operation beyond a doubt infinitely more dangerous than amputation? I think not. The practice is at present nearly exploded in this country; but I hear every now and then of its being adopted at Paris, and Mr. Crampton has thought it worthy of revival. The difficulties of his operations, however, and tediousness of the after-treatment, and, in particular, the general course and termination of one of his two knee-cases, as represented by himself, are sufficiently discouraging. No doubt more limbs might be saved by this practice than by that of amputation, but more lives would be lost. On this principle, I see no reason for preferring excision of the knee to amputation. Many interesting observations on the extirpation of various diseased joints may be found in the abovementioned dissertation by Wachter, and in the analysis of it by Langenbeck (*Bibliog. für die Chir.*, b. 3, Göttingen, 1811); likewise in Mr. Blackburn's paper, in *Guy's Hospital Reports*, vol. i.

The latter gentleman's conclusion, from a review of nearly all the cases on record, is, that excision is advisable in the shoulder and elbow; that it is admissible, though of doubtful utility, in the ankle; and that it is inadmissible, except under very peculiar circumstances, in the wrist, hip, and knee. (*Op.* cit., p. 298.)—C.]

K.

[KREOSOTE (from κρέας, flesh, and σωξω, I save). A new principle, discovered by M. Reichenbach in 1804 in pyroligneous acid and all the tars, and so named from its property of preserving animal matter. According to this gentleman, it is of service in caries, cancerous ulcers, rheumatic pains, and other diseases. It appears from Dr. Elliotson's researches that it has considerable power in checking vomiting, even that attending Asiatic cholera. He also found it of use in phthisis, epilepsy, diabetes, and neuralgia. "Of its external application (says he) I can speak favourably. When an ulcerated surface has required a stimulus, or when a slough, or unhealthy, perhaps offensive, discharge existed, I have seen it of great utility. As it prevents or arrests putrefaction, and removes all taint in dead matter, we cannot be surprised at its removing the offensive nature of discharges, whether from mucous membranes or ulcers, and preventing the injurious effects of diseased animal matter upon the part with which it is in contact. When the contents of the intestines have been very offensive, I have impregnated clysters with it advantageously; and I have employed it as a wash in mercurial fœtor, as well as ulceration, and in fœtor of various parts of the system. I have seen foul ulcers become clean, and ulcers of long standing have sometimes healed rapidly on its application." Dr. Elliotson bears testimony, also, to its efficacy in pruritus podicis, toothache, and porrigo. (See *Med. Chir. Trans.*, vol. xix., p. 217.) For external use, he says that from half a drop to two or three, diffused in water by means of mucilage, will usually be sufficient, though its application must be very frequent. I have tried it in a few examples of phagedenic ulceration in University College Hospital, and occasionally with success. I have known it used in the proportion of from three to eight or ten drops in each ounce of water. If given internally, it is best to begin with one or two drops, and increase the dose very gradually. In this way, one lady under Dr. Elliotson's care was able at last to take forty drops as a dose.

It is alleged that kreosote, as an external application, is advantageous in preventing the contraction of cicatrices, and that it is therefore useful in burns. (See *Sir F. Smith* in *Dublin Journ. of Med. Science*, vol. xi., p. 237.) "In different eruptions of a scaly nature (says this gentleman), kreosote has been found decidedly useful, and results the most favourable have followed its application to ulcers and solutions of continuity, having a venereal or scrofulous origin. From its known antiseptic properties, it has been recommended in gangrene." He also refers to its use in external and internal hemorrhages. Sir F. Smith tried it with success in phagedenic ulceration of the penis, disease of the septum narium, fistula in ano, tinea capitis, and cancrum oris. Sometimes he employed one part of kreosote to sixty of water; sometimes one of kreosote to sixty of acetic acid; and occasionally he brushed the edges and surface of ulcers with pure kreosote. His observations lead him to expect that kreosote would prove useful in cutaneous cancer and chronic ulcers of the cornea. Farther observations on kreosote will be found in *Edinb. Med. and Surg. Journ.*, No. cxviii.—C.]

L.

[LARYNGOTOMY. It consists either in puncturing the crico-thyroid membrane, as first proposed by Vicq d'Azyr, or in dividing, at the same time, the thyroid cartilage in the median line, as first suggested by Desault, or in dividing the cricoid cartilage and upper rings of the trachea, as originally recommended by Boyer. The last operation is sometimes termed *laryngo-trachcotomy*. To these methods is to be added that of making the opening through the hyo-thyroid membrane, as proposed by M. Malgaigne. 1. The first modification of laryngotomy consists in opening the inferior part of the larynx in the small triangular membranous space which lies between the thyroid and cricoid cartilages. The thyroid cartilage is exposed by dividing the skin and subcutaneous fascia: into the posterior surface of it, near the middle line, and at its lower third,

are inserted the thyro-arytenoid muscles and the chordæ vocales. The patient should be in the recumbent posture, with the head thrown back, so as to render the pomum Adami prominent. The incision should begin over the upper part of the thyroid cartilage, and be carried down to the cricoid cartilage. The crico-thyroid membrane having been exposed, the crico-thyroid artery is to be depressed with the nail, and the membrane opened directly above it. A probe-pointed bistoury, or the blade of a pair of blunt-pointed scissors, may then be introduced, with the edge turned upward, and the cartilage cut in the direction of the middle line, without inclining to the right or left, for fear of injuring the chordæ vocales. (See *J. F. Malgaigne, Man. de Méd. Opér.*, p. 488, ed. 2.)

Of the operation performed in the crico-thyroid membrane, Sir Charles Bell entertains a favourable opinion. He directs us to slit up the membrane, and open the incision with the handle of the knife, when the patient will immediately breathe with ease. Here, says he, there is nothing to alarm the most timid operator. No great turgid veins are opened; the cut is made above the thyroid gland, and above the anastomosing branch of the thyroid arteries. The part is strongly marked by the prominence of the thyroid cartilage above, and the ring of the cricoid cartilage below. "If the occasion be temporary, a simple slit of the membrane will be found sufficient. If necessary, a transverse cut will afford any degree of opening. If a round hole be desired, the four corners left by the incisions may be snipped off;" or the edges of the opening may be kept asunder by means of the doubled wire of a catheter, the middle part of which lies on the wound, while the ends are bent round the neck, and tied with a ligature behind. In Sir C. Bell's cases, less annoyance was caused by this contrivance than the tube.

2. *Laryngo-tracheotomy.*—As the lower part of the incision implicates the trachea, the isthmus of the thyroid gland must be cut; but the plexus of thyroid veins should, if possible, be avoided. Higher up, the knife passes through the skin, the fascia, the cricoid cartilage, and the crico-thyroid membrane, on which a small artery runs transversely. This it is desirable not to wound. The patient's head and neck being inclined back, so as to render the larynx prominent, an incision is to be made from the lower edge of the thyroid cartilage, and extended downward an inch and a half, so as to bring a portion of it over the trachea. As soon as the crico-thyroid membrane has been exposed, the artery is to be pushed upward with the nail of the left fore-finger; the larynx opened below the vessel; and then the cricoid cartilage, and three or four of the upper rings of the trachea, divided from above downward. (See *J. F. Malgaigne, Op.* cit., p. 488, ed. 2.)

3. *Laryngotomy through the Thyro-hyoid Membrane.*—This method has been proposed by M. Malgaigne. A transverse incision, about two inches in length, is made directly below the thyroid bone. With the second stroke of the knife, the platysma, and the inner half of each sterno-hyoid muscle, is divided. The point is then directed upward and backward, and the thyro-hyoid membrane divided in the same transverse direction, together with those fibres of it which proceed to the epiglottis. The mucous membrane is thus exposed, and at each expiration it protrudes through the wound. It is now taken hold of with forceps and divided, whereby the epiglottis is brought into view; and, being forced into the wound by the breath, is to be taken hold of with forceps or a hook, by which means the whole of the interior of the larynx will be exposed to view, and the instrument passed into it under the guidance of the eye. (See *Manuel de Méd. Opér.*, p. 489, ed. 2.)

With respect to the advantages of laryngotomy, Mr. Potter pronounces it to be "an operation unattended either with difficulty or danger, and will answer every purpose when the cause of obstruction is seated in the rima glottidis, or above it." (*On the Surgical Pathology of the Larynx*, p. 265.) A single opening in the crico-thyroid membrane would suffice for the introduction of a canula, for the purpose of enabling the patient to breathe; but for the extraction of foreign bodies, it would be necessary also to cut the thyroid cartilage. The fact that extraneous substances, when they are loose, are almost always lodged at the upper part of the larynx, proves that laryngotomy, in such cases, must commonly be most advantageous; and, according to Desault, even when the foreign bodies are lower down in the trachea, they may, in general, be most easily extracted with the aid of a pair of curved forceps.

"Of the three situations (says Mr. Lawrence) in which it has been proposed to make the opening, viz., in the thyroid cartilage, between that and the cricoid, or in the trachea, I consider the first as the least eligible. Besides the objections from the ossification of the cartilage, and the danger of wounding, or otherwise injuring, the chordæ vocales, there is the inconvenience in the case of angina laryngea arising from the swollen and thickened state of the membrane, which may actually impede the passage of the air. I am not aware of any objection to a transverse opening between the thyroid and cricoid cartilages. The prominence of the former in the neck serves as a guide to the part which should be opened. Whether bronchotomy or laryngotomy ought to be selected, must, of course, depend upon the nature of the case: in cases of cynanche, the proximity of the inflamed parts would be an objection to laryngotomy; while, in examples of foreign bodies within the glottis, this operation may generally be most advisable. It is absurd to think of confining one mode of operating to different cases." (See *Medico-Chir. Trans.*, vol. vi., p. 248.)

Laryngotomy, in Vicq d'Azyr's manner, seems to M. Velpeau to be most easily performed, and to have the advantages of implicating no part of importance, and of leaving the glottis uninjured; but when foreign bodies require extraction, the opening is too small for the introduction of instruments, and it would not admit a canula of sufficient size to let respiration be freely carried on. Hence M. Velpeau thinks favourably of the plan of opening the larynx more extensively, especially as no artery or vein of importance is in danger of being wounded. This, he says, is the only method of exposing foreign bodies, which mostly lodge in the rima glottidis, and of getting at polypi and other growths within the larynx. "Although an injury of the chordæ vocales (says he) is easy to avoid, and of little consequence, and although the voice is not more impaired by this operation than others, yet it merits preference only in the cases specified, and when the thyroid cartilage does not contain too much phosphate of lime." (See *A. Velpeau, Nouv. Elém. de Méd. Opér.*, s. ii., p. 207.)

As for laryngo-tracheotomy, which usually

leaves the thyroid gland uninjured, but wounds the crico-thyroid artery, M. Velpeau observes that it does not, like the method of Desault, enable the surgeon to see to the bottom of the larynx; and while it is too far from the bronchi to be convenient for the extraction of such foreign bodies as are not movable, it is too near the glottis for the safe employment of a tube. Hence, except when Desault's plan is especially indicated, M. Velpeau generally prefers tracheotomy.

Of M. Malgaigne's operation I cannot speak from experience; but, as being less simple than a division of the crico-thyroid membrane, or of this and the thyroid cartilage, it seems not to be entitled to general adoption, even where an opening very high up is desirable. Whatever considerations it may have in its favour in especial cases, depend upon its bringing the interior of the larynx more completely into view than is effected by other plans.—C.]

[Dr. Mott, of New-York, has opened the larynx between the thyroid and cricoid cartilages, for the purpose of admitting air in acute and chronic laryngical affections, with great temporary relief, but all the cases have been ultimately fatal. This is the candid concession of those who have adopted this expedient in untractable cases of croup, for which some of the transatlantic surgeons have so highly commended its utility and success.—Reese.]

[LIGATURES. Dr. Eve, of Georgia, employs exclusively ligatures made of the tendon or sinew of the deer, when he expects union by the first intention; they were originally suggested by Dr. John Bellinger, of Charleston, South Carolina. In all cases where suppuration is anticipated, neither these nor any other form of animal ligatures can be relied on. Silk ligatures are universally employed in America in such cases.—Reese.]

[LITHOTOMY. The first and most important step preparatory to deciding upon this operation is the introduction of the sound, which should be of steel, and the handle of which should be smooth, so as to enable the surgeon to detect more readily the first touch of the calculus. The importance of certainty in making out our diagnosis in cases of stone in the bladder, will be appreciated when we are reminded of the mistakes committed on this subject by the most eminent of the profession. In Dr. Norris's edition of Liston's Practical Surgery, several examples of these mistakes are recorded, in which lithotomy was performed when there was no stone; and, on the other hand, patients have been pronounced, after frequent sounding, to have no stone, and, dying of the disease, very large calculi have been found in the bladder. The great Cheselden lithotomized in three cases and found no stone; Dupuytren, Roux, Desault, and many other European surgeons, have committed the same error. It has several times happened in America, and in the hands of men of established reputation. Even Dr. Physick, than whom there never was a more cautious practitioner, came very near committing this sad blunder; for he says, "I sounded a patient, and had no doubt but that he had stone; his health, however, was bad, and I did not operate. He died soon after, and, upon examination, we found no stone."

In addition to the several directions given upon this subject in this Dictionary, the stethoscope is found to be an invaluable aid to diagnosis in those doubtful cases in which the surgeon finds it difficult to feel the stone. This instrument I have had occasion to use in two instances of this character, and we were enabled to hear the crepitus by placing the stethoscope upon the perineum, over the pubes, and even upon the sacrum, when the sensation was indistinctly felt by the sound, and wholly inaudible without this mode of auscultation. In both these cases the operation was performed in reliance upon this evidence of the presence of the stone, and, as the result proved, with propriety. In one of them, the prostate gland was greatly enlarged posteriorly, and the calculus occupied a sac immediately behind it, from which I failed to dislodge it by changing the posture of the patient, as suggested by Dr. Physick, placing him upon his head. So, also, the finger being introduced into the rectum while the sound was in the bladder, could not sufficiently elevate the calculus as to make it distinctly felt. Occasionally the convex portion of the sound would touch the calculus, and yet the next moment it was impossible to find it. But with the stethoscope the diagnosis became easy.

This object of recognising with certainty the presence of the stone, is not, however, the only result which should be sought in sounding; but we can frequently ascertain the number of stones, their size, consistence, and sometimes their configuration, and whether rough or smooth, in several of which inquiries the stethoscope will be found useful, and deserves more attention than has hitherto been bestowed upon it, not only in this case, but in fractures, as well as in probing for foreign bodies in the ear, nostrils, or other cavities, and also in gunshot wounds. Crepitus may be thus recognised in obscure cases with great readiness and certainty.

Dr. Physick's valuable improvement in the gorget, so highly appreciated by practical surgeons, does not appear to have attracted attention in Europe; it consists in having a movable blade, which can be removed for the purpose of sharpening. The same gentleman recommends the introduction of a large gum-elastic catheter into the bladder through the urethra, together with a long slip of lint into the wound between the lips of the prostate, in cases of secondary hemorrhage occurring after lithotomy. The pressure thus produced upon the wounded arteries of the prostate and the venæ vesicales may be continued for several days, and until suppuration commences; the urine meanwhile passes off by the catheter instead of flowing through the wound. Dr. Gibson has twice had occasion to adopt this expedient of Dr. Physick, and in both instances he thinks the patients would otherwise have perished.

Dr. Gibson has performed the lateral operation over fifty times, and has lost but six of his patients.

The high operation above the pubes was performed by Dr. Gibson for the first time in America, and it has since been repeated with success by Dr. M'Clellan, of Philadelphia, Dr. Carpenter, of Lancaster, and Dr. Van Valsah, of Lewisburg, Pennsylvania.

A case of calculus of so large a size that it could not be broken with the forceps occurred to Dr. Godman, at Cincinnati, some years since; and, after having cut down into the bladder, the operation was abandoned, it being found impossible to break or to extract it, because of its immense size. The wound healed up, and the man walked to Carlisle, Pennsylvania, where Dr. Given operated with the like result a second time. After his recovery he walked to Philadel-

phia, when, for the third time, Drs. Gibson and Physick performed the operation, and, finding the stone almost to fill the bladder, Dr. Gibson applied a drill half an inch wide, and made an opening large enough for one blade of the forceps, while, with the other, he soon quarried the stone and removed it. His patient recovered in two weeks, and again walked home, as Dr. Chapman remarked, "a stone lighter."

Mr. Cooper has made valuable additions to his article on the subject of lithotomy, which are here inserted.

[LITHOTOMY. It is correctly noticed by Sir Benjamin Brodie, that the symptoms differ, 1st, according to the size of the stone, the smoothness or roughness of its surface, and its general figure; 2dly, according to the quality of the urine. If the urine be unusually acid or very alkaline, and deposite the triple phosphate, it will be stimulating, and the symptoms of stone will thereby be aggravated; 3dly, according to the state of the bladder. Nothing aggravates the symptoms so much as inflammation of the mucous membrane; this increases the sensibility of the bladder a hundred fold, and causes a small stone to produce much greater distress and pain than a large one under ordinary circumstances. If the bladder be healthy, a very small stone may produce trifling and equivocal symptoms. The patient has rather more frequent occasion to make water; a sense of irritation, scarcely amounting to pain, referred to the neck of the bladder, urethra, and perhaps the hypogastrium, after the bladder has been emptied. In one instance, the patient complained for many months of nothing except an occasional and trifling pain in one of the groins, and of the urine being tinged with blood after riding on horseback. Bloody urine, after any jolting exercise, is a strong indication of a calculus either in the bladder or kidney. But this symptom is often absent in the early stage, while the stone is small, especially if the patient is leading an inactive life. (See *Sir B. Brodie on Dis. of the Urinary Organs*, p. 225, ed. 2.)

The pain in the glans penis and fossa navicularis is most severe after making water or exercise, when the stone suddenly falls down on the neck of the bladder. This pain "is one of the most marked symptoms of the disease. A child who labours under stone tells you of it, not in words, but in his actions. He is always pulling the end of the penis, and pinching it with his fingers, even so as to cause the prepuce to become elongated. You often find his fingers with the cuticle soft and sodden, as if they had been soaked in water, from the urine which has been imbibed." (*Op.* cit., p. 229.)

The degree of pain experienced by the patient depends not only on the state of the urine and bladder, but on the size, shape, chemical qualities, and situation of the calculus. "A patient with a simple lithic acid calculus suffers less than one with a calculus composed externally of the triple phosphate, and the latter less than one with a fusible calculus. The oxalate of lime, or mulberry calculus, on the whole, occasions more distress than the lithic acid calculus, probably on account of the irregularities which so frequently exist on the surface of the former; but it occasions less distress than calculi composed of the phosphates." (See *Sir B. Brodie, Op.* cit., p. 229.)

According to the same distinguished practitioner, patients with diseased prostate gland do not generally suffer more from stone in the bladder when it afflicts them, than other individuals, and perhaps less, in consequence of the swelling of the prostate gland hindering the stone from falling on the neck of the bladder. He has, however, seen three cases, in each of which there was a calculus in the bladder, complicated not only with an enlarged, but an ulcerated prostate; and the sufferings were in these instances horribly severe. In two of them lithotomy was performed; one of the patients died in five minutes after the operation, and the other became immediately comatose, and sank in a few hours.

OF CUTTING TOWARDS THE SYMPHYSIS PUBIS, AND THE BILATERAL OPERATION.

I have already made reference to the plan of dividing both sides of the prostate gland, as practised in 1804 by Dr. Physick, of the United States, and nearly thirty years ago by Sir Astley Cooper, with a beaked double-edged scalpel or a double-edged gorget, in cases where the stone was large, and since occasionally adopted by Sir B. Brodie and others. In 1816, Baron Dupuytren made trial of a method which had, indeed, been suggested at an earlier period by Chaussier and Béclard (see *Velpeau, Nouv Elem. de Méd. Opér.*, t. iii., p. 748), which consisted in making the first incision into the membranous part of the urethra, in a line with the raphe of the perinæum, commencing about two inches and a half in front of the anus, and terminating an inch from it. A second incision, made parallel to the first, divided the erector penis and the adipous cellular tissue, placed between the bulb of the urethra in front, and the rectum behind. In the third stage of the operation, the membranous portion of the urethra was laid open from the bulb to the verumontanum. The lithotome, or bistoire caché, was then introduced along the staff, and the latter withdrawn. The edge of the former was then turned upward towards the symphysis pubis, and the blade having been made to quit the sheath by pressing on a spring, the instrument was drawn out in this direction, so as to cut the neck of the bladder and part of its anterior parietes, the deepest portion of the upper side of the urethra, the superior part of the prostate, the cellular tissue between the anterior ligaments of the bladder, and the arterial and venous branches in this situation. (See *Clin. Chir.*, t. ii., p. 373.)

This method was soon abandoned; in fact, as the opening was situated in the narrowest part of the arch of the pubes, it must have afforded but little room for the extraction of the calculus. The venous hemorrhage would also be considerable.

In 1824, Baron Dupuytren began to employ his double lithotome with a staff that did not terminate in any *cul-de-sac*, which frequently impeded the disengagement of the lithotome from the deep groove of the instrument. The patient is placed in the usual position for the lateral operation, and the staff held by an assistant exactly in the vertical direction. While the left hand keeps the integuments of the perinæum tense, the right makes, with a double-edged knife, a semicircular incision, beginning on the right, between the anus and the ischium, and terminating at the corresponding point on the left, the distance to which it passed from the anus forward being five lines. The subcutaneous cellular tissue, the superficial fascia of the perinæum, and the anterior point of the external sphincter being divided, so as to expose the origin of the membranous part of the urethra, the groove of the

staff can be detected with the nail of the left forefinger, which will serve for guiding the point of the knife into it. During all this first stage of the operation, care must be taken to depress the lower edge of the wound with the finger, and to keep the rectum away from the edge of the knife.

After the membranous part of the urethra has been sufficiently opened, the same finger-nail serves as a guide for the lithotome, which, held in the right hand with the thumb below and the two fingers next to it above, is applied to the staff with its convexity directed towards the anus. The contact of the two instruments having been clearly ascertained, the surgeon takes hold of the handle of the staff with his left hand, and, raising its beak under the symphysis of the pubes, pushes the double lithotome along its groove into the bladder.

The staff is now to be withdrawn, and the lithotome turned, so as to make its concavity face the anus. Its blades are then made to quit the sheath, and it is drawn out, not exactly horizontally, but with an inclination downward. The left forefinger is then introduced into the wound, so as to ascertain the extent of the incisions made, and to guide the forceps to the calculus. (See *Dupuytren, Clin. Chir.*, t. ii., p. 390.)

Baron Dupuytren ascribed the following advantages to the bilateral operation:

1. The great facility of its performance.

2. The situation of the wound in the widest part of the lower aperture of the pelvis, and consequently the most favourable for the extraction of large calculi.

3. This method makes a shorter and more direct passage into the bladder, whereby the requisite manœuvring with instruments is facilitated.

4. The readier escape of the urine through the wound, and, consequently, the removal of any risk of its becoming extravasated in the cellular tissue.

5. An opening is made in the neck of the bladder and the prostate sufficient for the extraction of very large calculi, without the wound passing so far on each side as to become dangerous.

6. The ejaculator ducts are conceived by Dupuytren to be more safe from injury than in the common lateral operation.

7. The method is applicable to both sexes.

The bilateral operation had been performed about seventy times in the Hôtel Dieu and other parts of Paris, and only six of the patients died. In that hospital twenty-six patients were operated upon in succession with complete success. (See *Dupuytren* in *Clin. Chir.*, t. ii., p. 413.)

The double lithotome is now well constructed in London; and when the stone is known to be of ample size, the bilateral operation, I think, merits the preference to all ordinary plans.

A posthumous work, illustrative of Dupuytren's bilateral operation, and containing several interesting plates, has been recently published.

Mr. Liston is of opinion that no complicated machine is requisite to make this bilateral division, and that it is quite time enough to make such division when the necessity for it has been ascertained. "The single lateral incision affords sufficient room to admit of the removal of the stone in nineteen cases out of twenty, and there can be no purpose served, therefore, in always making a cut in both sides of the gland, and thus endangering the emasculation of the individual." (*On Practical Surgery*, p. 414.) I have already explained that several operators are in the habit of cutting the right side of the prostate gland with a knife when the stone is above a certain size.

TREATMENT AFTER THE OPERATION.

The position in which the patient should be placed after the operation, and the plan of leaving the wound uncovered, so as to let the urine readily escape, I have already described. Professor Jameson, of Baltimore, who aims at uniting the wound as far as practicable by adhesion, introduces a moderately large flexible catheter through the wound into the bladder, and secures it by a soft strip of rag to the penis. The patient is laid on his side, his knees brought together, and tied by means of a soft silk handkerchief. No sutures are employed, but the patient must lie quietly on his side for two or three days, so as to obtain the effect of a syphon from the tube. "He may, however, after some hours, if particularly desirous, turn upon his left side, yet never forgetting that the outer end of the tube must be lower than the inner. The patient may be kept comfortably dry by using a cup or large sponge to contain the water as it drops from the tube." (See *Amer. ed. of this Dict.*) A surgeon at Dundee has lately advocated the same practice.

Sir Benjamin Brodie had the misfortune to lose one patient from hemorrhage. The case was that of an old man, who had an enlarged prostate and an unusually deep perineum. The blood was venous. If the incisions are made low down, and not too extensive, the chance of hemorrhage seems to Sir B. Brodie to be but trivial. (*On Dis. of the Urinary Organs*, p. 298.) In one example under this gentleman, where the size of the calculus made it necessary to cut the right side of the prostate, the hemorrhage would have proved fatal if an assistant had not pressed the internal pudic artery against the bone with his finger for several hours. In another case, operated upon by Sir E. Home, the bleeding was first suspended by pressure with the finger, and then, as the patient was a thin person, Sir B. Brodie succeeded, with the aid of a small flexible silver needle, in passing a ligature round the trunk of that artery. Dr. Physick, of the United States, once succeeded in tying the internal pudic artery after lithotomy. (See *Reese in Amer. ed. of this Dict.*) Secondary hemorrhage sometimes occurs after lithotomy, and probably, as Sir B. Brodie suspects, from the separation of a slough. In one such case, Mr. Earle stopped the bleeding by introducing into the bladder, through the wound, a tent of lint, enclosing an elastic gum catheter.

Mr. Key believes that the pudic artery itself is rarely wounded; but that in adults, the artery of the bulb and the superficial perineal branch often bleed profusely. If the incision be made low down in the perineum, he admits that the artery of the bulb may escape; but, from experiments which he has made on the dead subject, he infers that it is almost always divided. He does not approve of plugging the wound with lint or sponge introduced on a catheter. "The cellular membrane is irritated by it, and an unhealthy form of inflammation ensues; while the catheter being soon blocked with coagulum, does not carry off the urine from the bladder. I have, however (he adds), found advantage in checking the bleeding by means of pressure made upon the upper part of the left side of the perineum by

a forked piece of lint fixed to a piece of cork. Pressure in this mode also reaches the deeper branches of the prostate, from which the blood sometimes oozes for a long time after the patient is placed in bed, and distends the bladder with masses of coagula." (See *Guy's Hospital Reports*, vol. ii., p. 19.)

I have seen the rectum wounded in three or four instances, but no serious consequences were the result. A wound of the bowel, occurring as it does close to the sphincter, does not appear to Mr. Key to be a matter of serious moment.

I shall conclude this article with the following quotation. "Some individuals (as Sir B. Brodie observes) are good subjects for the operation, and recover, perhaps, without a bad symptom, although the operation may have been very indifferently performed. Others may be truly said to be bad subjects, and die even though the operation be performed in the most perfect manner. What is it that constitutes this essential difference between these two classes of cases? It is, according to my experience, the presence or absence of organic disease," especially of the kidneys or bladder. (*Op.* cit., p. 301.) The enlargement of the prostate gland in old men, I believe with Sir B. Brodie, does not increase the danger, though it may the difficulty of the operation. I infer this from a case which occurred in University College Hospital, and in which the patient recovered without any bad symptoms, though the operation was excessively long, and a portion of the enlarged gland, which had been sliced off, fell down upon the floor.

With respect to fistula in perinæo, impotency, and incontinence of urine, as consequences of lithotomy, I have seen two or three examples of the first. Mr. Key has not witnessed fistula as a consequence of the operation for vesical calculus. "The operation of extracting prostatic calculi (he observes) when they are large, and the gland diseased, is sometimes followed by difficulty in healing the external incision, and the formation of a fistula, through which some drops of urine escape. But in lithotomy, the incision being made through healthy structures, heals quickly by a healthy process of granulation, and fistula is therefore a very uncommon occurrence." Mr. Key has known of one instance in which impotency was ascribed to the operation. But, according to his experience, incontinence of urine rarely occurs in the adult. "In the young subject, partial incontinence will sometimes occur if the patient is allowed to leave his bed too soon after the operation, before the neck of the bladder is firmly healed, and the sphincter has recovered its tone. Instances, therefore, are met with of young boys, who, if they retain their water inconveniently long, find it dribble away as they move about. In bed, the urine is perfectly retained. When they arrive at the age of puberty, the power of retaining it becomes increased." (See *Aston Key, in Guy's Hospital Reports*, vol. ii., p. 25.)

Lithotrity (from λιθος, a stone, and τερεω, I pierce). *Lithotripsy* (from λιθος, and τριβω, I break). The reduction of a calculus in the bladder into small pieces by means of instruments passed into that organ through the urethra, so that the fragments may be discharged through the latter tube, and no necessity remain for the performance of lithotomy. Although the history of lithotrity goes back to a remote period, the practice of it cannot be said to have been established more than a very few years. The idea of breaking calculi to pieces was entertained in the days of Albucasis (*Liber. Theor.*, p. 94, 1519), but, as my friend *M. Leroy d'Etiolles* justly observes, there is no record of the plan having been actually practised at the period alluded to; and Alexander Benedictus, of Verona, who published in 1533, mentions the scheme only to condemn it. If it be admitted, however, that the Egyptians sometimes broke stones in the bladder, it must be granted that they have left their successors perfectly uninformed about their method, which stood in need of being revived anew. (See *Mem. de la Lithotripsie, Mem.*, i., p. 113, 8vo, 1836.) The earliest proposal for breaking a stone in the bladder without incision, noticed by Haller (*Biblioth. Chir.*, t. i., p. 313), was made by Sanctorius. M. Leroy, on referring to the text of this author, believes, however, that it relates, not to the use of any instrument like *la pince à trois branches*, with a drill in its centre, but merely an invention calculated to extract small stones through the urethra. As for the instrument of Fabricius Hildanus, resembling the bullet extractor of Andreas à Cruce, M. Leroy conceives that it can have but an indirect connexion with the history of lithotrity, since Fabricius only employed it for the removal of calculi lodged in the anterior portion of the urethra, and not for the extraction of those of the bladder.

Thus, down to the beginning of the 19th century, no description of any mode of breaking calculi had yet been published. It is alleged, indeed, that successful attempts had sometimes been made before this period by patients on themselves. Thus, a monk of Citeaux is alleged to have succeeded in breaking a calculus in his bladder by introducing a rod of iron through the urethra, terminating in a chisel, and striking its outer end with a hammer. Major Martin pulverized his own calculus by means of a file fixed at the end of an iron rod. (*Marcet on Calculous Disorders*, p. 20, fig. 5.) M. Leroy doubts whether any complete cures were truly thus effected; and refers to some later accounts, by which it appears that Major Martin actually died of stone in the vicinity of Calcutta. Nor does this eminent lithotritist attach more importance to the statement, that Rodriquez, a physician at Malaga in 1800, broke a stone by striking it with a catheter; or, if this were really done, he infers that the calculus must have been either very small or brittle, and that few could have been thus broken.

Lithotrity was first seriously proposed in 1812, as a means of mechanically breaking stones in the bladder, and then only as an auxiliary to the chemical dissolution of them, the practicableness of accomplishing which the writings of Fourcroy and Vauquelin had raised hopes of. The manner of doing it was suggested by Gruithuisen, a Bavarian surgeon. His apparatus consisted of a wide, straight tube, through which he passed a noose of copper wire, and a rod ending in a circle of teeth, or a spear point. The calculus was caught hold of, and fixed with the wire, and then the circular saw, which was put in motion by means of a bow, was designed to perforate it. The important fact, first demonstrated by Gruithuisen, is the practicableness of introducing straight catheters of large size through the urethra into the bladder, so as to facilitate the necessary measures requisite for the mechanical destruction of calculi.

Some years afterward, Mr. Elderton published in the *Edinb. Med. and Surgical Journ. for April*, 1817, a description of a curved instrument, which

admitted of being opened for the seizure of the stone, and was furnished with a kind of file, that acted by an alternate movement. But the two branches were found insufficient for fixing the calculus, and the bladder was not out of danger of the action of the file. Things had gone thus far when the sheath-forceps, with three blades and a perforator (*la pince à trois branches, à gaine et à foret*), were invented in 1825 by M. Leroy, exhibited by him to the Academy of Surgery, and first tried, and this with success, upon the living subject by M. Civiale in the following year. In short, after a formal investigation of the merits of the several parties who led the way in these improvements, the Academy of Sciences adjudged one prize to M. Civiale for having first performed the operation on the living subject; one to M. Leroy for the invention of the process which first answered in practice; and another to Baron Heurteloup for the improvements made by him in the operation. (See *Leroy d'Etiolle, De la Lithotripsie*, 8vo, Paris, 1836, p. 114.)

An impartial reader, who reflects upon this history, will perceive, then, that lithotrity has attained its present perfection by the talents and ingenuity of many labourers; and that, while the merits of MM. Leroy, Civiale, and Baron Heurteloup stand exceedingly high, the originality of the scheme, if not of the practice, is to be traced in ancient writers, and the meritorious inventions of Gruithuisen and Elderton will never be forgotten, though not honoured with the prize or commendation of any public body.

It is not my intention in this edition to describe the many instruments proposed for lithotrity, because I know that no account of them would be intelligible without plates, and some of them are no longer used. A clear and excellent description of them, illustrated by woodcuts, has been published by M. Leroy, to which I would particularly refer. (*De la Lithotripsie, Mem.*, 8vo, Paris, 1836.)

The necessity for my entering into the particular merits of the very numerous instruments constructed for pulverizing and crushing calculi in the bladder, appears now, indeed, to be needless, because the operation, as first performed on the human subject by M. Civiale with the canula, three tenacula, and the drill of M. Leroy, has been nearly superseded by the more simple and expeditious method first executed by Baron Heurteloup. In this improved operation, the patient is placed upon an operation-bed or table which admits of being raised into an oblique plane. At the foot of it is an apparatus which affords a fulcrum to the instrument after its introduction into the bladder. The head of the bed, and, consequently, the fundus of the bladder, may be depressed to any extent desired, the legs which support it having hinges, and capable of folding. On this couch the patient is placed nearly in the position usually chosen for the lateral operation. A strap is passed round the shoulders and buckled to the sides of the table, and the feet are placed in slippers securely fixed at the foot of the bed.

A catheter of the usual length, with a short and rather abrupt curve, is introduced. It serves first as a sound for ascertaining the situation of the calculus, the shortness of the curve facilitating its motions in the bladder. It is furnished with a stopcock. The bladder is next moderately filled with warm water by means of a silver syringe, furnished with a ring on each side of the syphon for the insertion of two fingers, so as to render the instrument manageable with one hand. The bladder must not be painfully distended with water, because then its action would be excited, and the fluid would be expelled again. A pair of strong sliding forceps, the opposite surfaces of which are furnished with teeth, are then introduced, and the calculus having been seized, the lower piece of the forceps is fixed to a vice at the foot of the bed, serving as a fulcrum, and the upper piece is struck with a hammer, and the calculus broken. Thus neither the shock arising from the concussion is communicated to the bladder, nor is this organ liable to be injured by the fragments being forcibly projected against its internal surface. The instruments are then withdrawn, and the fragments are afterward voided with the urine. If any fragments remain incapable of being thus discharged, the operation is repeated from time to time, as often as may be necessary.

On the subject of the comparative advantages of lithotomy and lithotrity, it is somewhat difficult to form at present a definitive judgment, because the advocates for one or the other proceeding seem to be too much under the influence of prejudice; and in France a degree of animosity has mingled itself with the question, seriously interfering with any just conclusion. When the practice of lithotrity and lithotripsy first began, a few years ago, it was extolled as perfectly free from danger, and capable of superseding lithotomy altogether. This representation is incorrect. M. Velpeau declares that lithotrity is generally a longer and more painful business than lithotomy; and that he has known some patients who had been cut for the stone by M. Souberbielle, after having tried lithotrity under the care of M. Civiale, confess that one sitting for the latter was more painful than all the requisite proceedings in lithotomy. From what I have seen of lithotrity, as practised by Baron Heurteloup, I should say that lithotrity, with some few exceptions, is infinitely less painful than lithotomy; and that many patients, after its performance, follow their common occupations as usual. Two or three years ago, the baron was kind enough, at my request, to exhibit his skill on three patients, in the anatomical theatre of University College, in the presence of all the students and many visiters. The manœuvres were executed with surprising precision and quickness. These patients, who had undergone some previous sittings, seemed to feel little pain; and, I should say, appeared to submit to a repetition of the operation with the most cheerful readiness. Still it is not an operation always free from great suffering and danger, nor is it applicable to all cases of stone.

According to the researches of M. Velpeau, one third of the patients who undergo lithotrity experience bad symptoms, and it sometimes proves fatal, as we are well aware of in Great Britain. Baron Heurteloup has proved that M. Civiale lost 8 patients in 48, and M. Leroy 3 in 28; and M. Velpeau alleges, that an inquiry into the results of lithotrity, in all parts of the world, will not make the average success of lithotrity greater. M. Velpeau adds, that if all the calculous patients be taken into the account who have undergone lithotrity, and on whom lithotomy might have been practised, the result is still less favourable; for of 82 spoken of by M. Civiale, 31 died within a year after the operation, and 19 did not recover without having experienced severe symptoms. Of 40, M. Leroy only radically cured 25. Of 10, M. Bancal could only operate

upon 2. Hence M. Velpeau infers that at least 1 dies out of every 10 or 12 who submit to lithotrity; but that, if a considerable number of individuals, taken promiscuously, were to be subjected either to lithotomy or lithotrity, the average number of deaths would comprise at least one sixth or one eighth of the whole of such individuals.

Yet M. Velpeau admits that, on the whole, lithotrity is a less dangerous operation than lithotomy. On this point I entertain, with him, a full conviction in reference to the mere operation. Who can, indeed, set down the manœuvres required in lithotrity, according to the best mode of performing it, as generally to be compared, in regard to danger, with the operation of cutting into the bladder? But this does not settle the question; for, though the operation itself may be infinitely less dangerous, the less radical nature of it, the fragments left behind, and their irritation of the bladder, which is often in a very unfavourable state to bear the continuance of such irritation; the greater chances of relapse, &c., are weighty considerations, which cannot be overlooked. Another fact, very necessary to be remembered in forming a judgment of the merits of the two operations, is, that the individuals most fit for lithotrity are exactly those on whom lithotomy would prove most successful; while those to whom lithotrity is not suitable would have a bad chance of cure from lithotomy. I would not go so far, however, as M. Velpeau, who states that they would have an inferior chance (*Nouv. Elem. de Méd. Opér.*, t. iii., p. 994), because I apprehend that where the bladder is diseased, or its lining affected with chronic inflammation, promptly taking away the stone altogether is better than breaking it, inasmuch as leaving the fragments of it behind, to keep up irritation for a time, must be particularly disadvantageous. Even were lithotrity proved to be decidedly less dangerous in its results than lithotomy, generally speaking, it is certainly not applicable to all cases. It is quite unfit for calculi formed upon extraneous substances, which serve as nuclei; for encysted or adherent calculi; for such as are excessively hard, like some of those composed of oxalate of lime; for calculi above a certain size; for patients whose urethræ, from malformation or disease, will not allow the proper instruments to be introduced. If there be several calculi, an enlarged prostate gland, or a diseased bladder, M. Velpeau pronounces lithotrity to be at least as dangerous as lithotomy. Its general advantages, however, under other circumstances, he deems incontestable, except in children; and, though more liable to be followed by relapse, on account of the fragments sometimes eluding the most careful examinations, he gives the preference to lithotrity if two, three, four, five, or even six repetitions of it promise to be effectual. (See *Velpeau, Nouv. Elem. de Méd. Opér.*, t. iii., p. 904.)

Lithotrity, as practised by Baron Heurteloup, appears to Sir Benjamin Brodie to have several advantages over lithotomy. It is less formidable to the patient. It requires little or no confinement; and many individuals will be induced to submit to it at an early age, who would not muster courage to submit to lithotomy until their sufferings had become excessive, and circumstances arisen to render the operation dangerous. This is a point likewise insisted upon by M. Leroy, Mr. Aston Key (*Guy's Hospital Reports*, vol. ii.), and many other writers on lithotrity. There is no danger of hemorrhage, nor of those ill consequences which arise from an incision or laceration extending into the cellular texture around the neck of the bladder. (*On Dis. of the Urinary Organs*, p. 316, ed. 2.)

The following appear to Sir B. Brodie to be the principal disadvantages of lithotrity. The patient does not obtain a cure at once; and, in many instances, the process by which the stone is crushed requires to be repeated several times. As the smallest fragment which remains behind will form the nucleus of a new stone, a recurrence of the disease is more likely to take place after the lithotriptic operation than after lithotomy, especially in those cases in which, in consequence of an enlargement of the prostate gland, the patient is unable completely to empty his bladder. The operation is only adapted to calculi of moderate size; and, when applied to larger, is either impracticable or difficult, tedious, and painful. When the stone is large, the sharp, irregular fragments lying in the bladder induce inflammation of its lining membrane, attended with severe local suffering, and much disturbance of the general system, either retarding the cure or terminating in death. The complications of disease in the kidney, or bladder, or ulcerated prostate, which render lithotomy hazardous, make lithotrity also hazardous. As for the comparative pain, it is so different in different examples of each practice, that there is difficulty in forming an opinion on this point. In general, after either of the operations, the patient says that he suffered less than he expected, that is, if the bladder is healthy, and the operation proceeds favourably. If the bladder be inflamed, or anything occurs to render the operation difficult and tedious, the patient undoubtedly suffers severely, whether the stone be crushed or extracted by incision. Sir B. Brodie then adverts to the sliding forceps shown to him about the year 1824 by Mr. Weiss, which were intended to crush calculi in the matter by means of the pressure of a screw instead of a hammer; and (says he) as it is now constructed, it seems capable of doing all that can be done with the hammer, unless the calculus be very large, and then the propriety of having recourse to lithotripsy in any form is very problematical. The forceps invented by Mr. Weiss are highly deserving of notice, not only on account of their usefulness, but their priority to the percussor, and some other means for crushing calculi in the bladder. It will be also found convenient, when the stone is small enough to admit of being drawn a certain way into the urethra, and crushed there. For this purpose a pair of sliding forceps may be used, first without a screw, but to which it may be adapted in the course of the operation. (See *Brodie on Dis. of the Urinary Organs*, p. 348.)

Previously to puberty, lithotrity is more difficult of execution than in the adult, in consequence of the narrowness of the urethra, the unmanageableness of the patient, and the exquisite sensibility of the parts. Instruments of more than two lines, or two lines and a half in diameter, cannot be introduced, and, on this account, they cannot possess much strength. (See *Velpeau, Nouv. Elem. de Méd. Opér.*, t. iii., p. 893.) However, that lithotrity is practicable on children under the age of six years is sufficiently proved by some cases recorded by M. Segalas (*Revue Med.*, Août, 1834), and by other examples in which that very distinguished lithotritist M Leroy was the operator. Yet, in one instance under him, a piece of the forceps broke off, which, however, he succeeded in extracting a few days afterward by means of another forceps. But a

fragment of the calculus now passed into the urethra, and at first could not be pushed back. Afterward it was reduced into the bladder by Dupuytren, who then performed the bilateral operation for its extraction. (See *M. Leroy, De la Lithotripsie, Mem.*, 8vo, Paris, 1836, p. 237.) The reason why cutting into the bladder was here preferred by Dupuytren to merely dividing the urethra for the removal of the stone I do not understand. It is only justice to my friend M. Leroy to state, that he candidly admits that for children lithotrity should not be preferred to lithotomy, unless the calculus be known to be of small size. In them lithotomy is attended with little risk of dangerous bleeding, effusion of urine, peritonitis, or cystitis, and the operation is completed in a very short time. In infancy, among other considerations against lithotrity are, first, the high situation of the bladder in the pelvis, which greatly increases the curvature of the posterior third of the urethra; and, secondly, the encouraging chances of success from lithotomy at this tender period of life. For a corroboration of the doctrine that lithotomy is preferable for children, I refer also to the arguments of Mr. Aston Key. (See *Guy's Hospital Reports*, vol. ii.) One of this gentleman's inferences is, that lithotomy should be generally preferred in children and elderly subjects.

In some persons, the condition of the prostate gland pushes the urethra up behind the symphysis pubis, and renders lithotrity very difficult. For obviating this impediment, M. Leroy invented a contrivance (*redresseur de l'urethre*) for rendering the passage straighter. It consists of an elastic gum catheter, which is first introduced curved, and then straightened by means of a rod (mandrin), which is slowly propelled into it from before backward with a screw. But, as M. Velpeau observes, there is danger of contusing the verumontanum with this instrument, or of lacerating the posterior side of the urethra. Another instrument of this kind, invented by M. Tanchou, seems to M. Velpeau safer, as the third of it towards the bladder consists of little pieces articulated together, so that the instrument admits of being first introduced curved, and then straightened. (*Nouv. Elem. de Méd. Opér.*, t. iii., p. 894.) But, now that the breaking of calculi in the bladder is usually effected with the sliding forceps, acted upon by a screw or the hammer, and such instrument is necessarily curved, these inventions for facilitating the introduction of straight instruments are of less importance than they were a few years ago.

Among the occasional ill consequences of lithotrity, the severity of the pain is sometimes dwelt upon, though, as I have already stated, the pain complained of varies in different individuals for reasons already hinted at. Until lately, much of the pain frequently depended upon the action of straight instruments, which forcibly stretched the subpubic portion of the urethra; and, as M. Velpeau remarks, the use of curved instruments will remove this cause of suffering.

In some cases, each application of lithotrity is followed by a paroxysm of fever. It is an accident that may follow the most simple use of a catheter or bougie: it often renders it necessary to prolong the intervals between the repetitions of the operation. In many cases, the spermatic cord and testicle swell, owing to the contusion and irritation of the verumontanum, and terminations of the common seminal ducts. Lacerations of the urethra, urinary extravasation, and abscesses in the perineum and scrotum, have also been occasionally noticed. I know of one case myself, in which the patient died of effusion of urine.

In some instances, cystitis, peritonitis, and fatal nervous disorder arise from injury of the bladder with the forceps, or the irritation caused by the sharp angular fragments. I know of two or three instances in which the patients were seized with violent universal spasms directly after the operation, and expired in the course of a very short space of time after their removal from the table. In other cases, incontinence of urine, or paralysis of the bladder, has ensued. In many instances, the fragments enter the urethra, and cause retention of urine, accompanied by severe suffering.

M. Breschet witnessed an instance in which the bladder was perforated, and I have heard of a similar accident in London; though, as M. Velpeau justly observes, such an occurrence ought to be exceedingly rare with a circumspect operator.

The pinching of the bladder, another accident, may in general be avoided with tolerable certainty by not suddenly closing the lithontriptor until the calculus has been felt to be grasped by it, and the instrument has been first drawn a little way towards the vesical orifice of the bladder. The last accident, and not the least serious, to which lithotrity is liable, is the breaking of the instrument in the bladder, or such a bending of it that it cannot be withdrawn through the urethra. In the first case, lithotomy becomes indispensable; in the second, it may become necessary to cut down to the instrument in the perineum, and divide it with a file, before it will admit of removal. I know of instances in which such things have been exemplified.—C.]

[*Lithotripsy* has already merited the admiration and eulogy of many of the transatlantic surgeons, and has been often successfully employed in the United States, where it is regarded as, in certain cases of stone, greatly to be preferred before lithotrity.

Among those who have been enamoured with this new operation, and have done much towards introducing this improvement into the United States, Professor Gibson, of Philadelphia, deserves honourable mention. This eminent surgeon has always contended that lithotrity is a difficult operation, requiring great dexterity, a perfect familiarity with the use and knowledge of the mechanism of the complicated instruments, and, withal, a full supply of the instruments adapted to so many purposes, and hence within the reach of but few surgeons. He has therefore protested against the notion that "lithotrity is so very easy and simple that it may be performed successfully by those who would not dare to venture on lithotomy." The frequent failures of surgeons both in Europe and America have served to fortify his opinions, and confirm the propriety of his judgment, for even in the hands of Dr. Physick lithotrity has been followed by diastrous results. At the same time, Dr. Gibson does not undervalue the merits of this brilliant discovery, and he awards to Civiale extraordinary skill, tact, and success in the use of his own instruments, in which respects, however, he has few equals; but he insists that for success very great skill is demanded in the operation, very perfect instruments in regard to their construction and temper, but, above all, most accurate discrimination as to the cases to which it is adapted.

But lithotripsy he regards as within the reach of a much greater number of surgeons, less painful to the patient, attended with little or no risk, if suitable care be used in selecting the cases and in employing the instruments, provided the patient will submit to the necessary restrictions; and he thinks, under favourable circumstances, it is certain of success.

Lithotripsy proposes two objects, viz., crushing and percussion. The former of these processes is adapted to soft and friable stones, the latter to those which are hard and compact. Several instruments have been invented for this operation, but the two most generally preferred are those of Baron Heurteloup and M. Jacobson. For an accurate description of these instruments, and a critical examination of the merits of each, reference may be had to Dr. Gibson's Institutes of Surgery, last edition, which is illustrated by very accurate drawings, which it is impracticable to give here. Preference is here given to the instrument of Heurteloup, for reasons which are assigned at length. When the stone is small and has not existed very long, and if the patient be an adult having in other respects a sound constitution, and the bladder and urethra be not remarkably irritable, lithotripsy may be performed with every probability of success, and in such cases should be preferred to lithotomy or lithotrity; but, on the contrary, in the absence of these favourable conditions, and especially under an opposite state of things, especially if the stone be large, hard, and rough, and the constitution have greatly suffered, the chances of recovery would be greater by lithotomy. Especially in children, no operation other than lithotomy should be attempted, and happily, in such cases, there is little to fear from the lateral operation, as the almost uniform success attending it on boys amply shows. The operation of lithotripsy, however, is adapted to those frequent cases of adults and aged people who suffer from stone, while the constitution has not yet essentially suffered, nor the bladder become diseased, nor has the stone acquired a large size. The pain and danger being inconsiderable, such persons, on being informed of the advantages of lithotripsy, might be induced to submit to it early, instead of delaying, as they are wont to do, until so late a period that but little chance remains of success by either operation.

For lithotripsy, Dr. Gibson regards a preparation of the patient necessary by rigid dieting and depletion, unless it be contra-indicated. He thinks it important that very low diet, with occasional laxatives, should be enforced, for weeks in some cases, as preliminary to attempting lithotripsy. A very minute account of the successive steps in the operation will be found in his work already referred to, and our limits will only allow of a brief reference to his cases, which may be found in the American Journal of Medical Sciences for 1837. It will be there seen that Dr. Gibson has reported five cases, in three of which he was completely successful by a repetition of the operation of lithotripsy, and in one of which he succeeded but partially, owing to the long existence of the disease and his lithic diathesis. With a candour which, however worthy of imitation, is rarely exhibited, he gives the details of a fatal result of one operation, which he ascribes in part, and not without reason, to the ungovernable habits of the patient as regards indulging his appetite. In all these cases he used Heurteloup's instrument, though in one of them he had previously tried that of Jacobson, at the instance of the patient, who preferred it, until, by the suffering it inflicted, he gave up his preference, and then experienced the advantages of the other, by which he was completely cured.

Dr. Randolph, of Philadelphia, and Prof. Nathan R. Smith, of Baltimore, have been successful in the use of Jacobson's instrument, although both these surgeons have since adopted Heurteloup's, and now prefer it in performing lithotripsy.

I have only room to add, that after enumerating his objections to the instrument of Jacobson, while, nevertheless, admitting its several points of merit and admirable ingenuity, Dr. Gibson gives the following reasons for his decided preference to that of Heurteloup. 1st, In addition to its working upon the principle of gradual pressure, it combines the important power of concussion; 2d, It does not give so much pain either in introducing it or manœuvring it in the bladder; 3d, It can grasp a larger stone; 4th, Its beak can descend behind the prostate, and enter every corner or pocket of the bladder; 5th, It is extremely well adapted to seek out and pick up fragments; 6th, It is impossible to pinch the bladder, were the surgeon even disposed to do it; 7th, It would be next to impossible, when well tempered, to break it, though Jacobson's chain is possibly still stronger; 8th, The liability of the groove in the female rod to become clogged with sand and small fragments, so as to give the patient pain in withdrawing the instrument, is obviated by a little practice, by opening the forceps, and by slight lateral movements, washing out the fragments, and afterward crushing the remainder by a few taps of the hammer. The large window lately introduced at the extremity of the instrument, moreover, completely overcomes this difficulty.

It is but just to add, that there are some surgeons who still give the preference to the other instrument. Dr. Norris, in his late edition of Liston, says, "The 'brise pierre articulé' of Jacobson is the instrument generally(?) made use of in this country. It combines great power of action with delicacy of form and structure; and if by accident it should be broken, an instance of which I am not aware of ever having happened, it may be withdrawn without that difficulty which has occurred with the instrument of Heurteloup. Besides, it can seize as large a stone as the other, is not so liable to pinch the bladder, catches more easily, and holds firmly the calculus when included."

In England, both these instruments have been superseded by the screw lithotrite of Mr. Weiss, a graphic description of which will be found in Dr. Flint's edition of Druitt, lately published, as also in Dr. Norris's edition of Liston.

Dr. J. C. Warren has performed the lateral operation of lithotomy 18 times, and succeeded in all but two. He has only attempted lithotrity once, and then with complete success.

Dr. Ozier, of Charleston, divided both lobes of the prostate in lithotomy some years since, and Dr. Eve, of Georgia, did so last September, using Dupuytren's double lithotome cachée, and extracted a large stone of the mulberry species. In one of Dr. Warren's cases, lately reported in the New-York Lancet, both lobes of the prostate were divided.

Professor Dudley, of Kentucky, has perhaps excelled, both in the number and success of his operations, any other surgeon in America, hav

ing, as early as 1838, performed the lateral operation of lithotomy 170 times, and only four of these failed to recover by the supervention or aggravation of other diseases. His extraordinary success has been attributed to his careful selection of cases upon which to operate, which, if true, as alleged, is highly complimentary to his discrimination and discernment; while others ascribe it to the preparation to which he subjects his patients prior to the operation, and which, it seems, consists mainly in restoring the digestive organs by suitable medication, another evidence of his science and skill.

In Dr. Bush's able paper on the subject, published in the Transylvania Journal, however, it will be seen that, though Professor Dudley does not claim any novelty in his operations, yet there are peculiarities, nevertheless, which entitle him, by comparison with other surgeons, to the merit of novelty. I regret that my limits will not allow me even to indicate the features of his operation, which I regard as meritorious, nor is it necessary to vindicate the claims to which his unparalleled success entitles him, as in this operation pre-eminent among surgeons. I only regret that my failure to hear from him has deprived me of the ability to do him justice, by recording his skill in other departments of operative surgery to the extent he deserves.

By Dr. Flint's edition of Druitt, lately published, it appears that Dr. Dudley invariably uses the gorget for the prostatic section; and in employing this instrument, he is almost alone in America, and yet his astonishing success might be urged as an argument in its favour. Most American surgeons, instead of the gorget, employ either the bistoury or Mr. Liston's elongated scalpel, with a cutting edge, extending from the point to about midway of the blade; and Dr. Flint employs this latter instrument for all his incisions in lithotomy, from the integument through to the bladder. A valuable paper on the nature and treatment of calculous disorders, in review of Dr. Dudley's pamphlet, may be found in the Amer. Journ. for 1837.

Dr. Alban Goldsmith, of New-York, has performed the lateral operation of lithotomy 58 times, and has been successful in all but three; and the failure in these were attributable to complicated disease and advanced age, the cases being most unpromising. Dr. Goldsmith has performed lithotrity three times, and lithotripsy six times, with invariable success. Three of these cases were children.

Dr. Mutter prefers a grooved staff, very slightly curved, in the operation of lithotomy, and he uses a common scalpel for all the incisions. He has had great success in the treatment of stone, both by cutting and crushing. For this last purpose he prefers Jacobson's instrument.

The merit of being the first in the United States to perform the operation of lithotrity is due to Dr. Depeyre, of New-York, and the successful case is reported in the New-York Med. Journ. for February, 1831. He employed the instrument of Civiale, and practised his method. Dr. J. Randolph, of Philadelphia, in the year 1834 reported six successful cases of lithotripsy by Baron Heurteloup's method, in conjunction with the plan of Civiale, so that Dr. Randolph was the first in America to succeed with lithotripsy. In 1836 he reports in the same journal seven additional cases, and in 1837, four more, all successful.

Dr. George M'Clellan, of Philadelphia, has now performed the high operation for lithotomy nine times, and the lateral operation twenty-one times, with uniform success, five of the latter being females. He has repeated lithotripsy thirteen times, and has only failed in one case. Dr. J. Rhea Barton, of Philadelphia, has several times tried lithotripsy, but he thinks there are but few cases of stone to which it is adapted, and that but few surgeons will ever excel in this method, because of the tact it demands, and which can only be acquired by long experience and frequent opportunities, such as rarely fall to the lot of any individual in this country. Dr. J. Randolph, of Philadelphia, was among the first in this country to cultivate the arts of lithotrity and lithotripsy, and has been more successful than any other surgeon in the United States, both in adults and children.

Dr. J. Rhea Barton has performed the lateral operation of lithotomy thirty-six times, of which he has lost four patients, all of which were unpromising cases in their previous aspect, but the operation affording, nevertheless, the only chance of giving possible relief, three of the patients being of very advanced age, and worn out by the long continuance of the disease.

Dr. Nathan R. Smith, of Baltimore, has operated in forty-five cases demanding the lateral operation for lithotomy, of which he has lost but three. He has also treated eleven cases of stone in the bladder by lithotripsy, in all of which he has been completely successful, except in one very unfavourable case, in which no form of surgery offered any hope of success. This eminent surgeon has applied his extraordinary mechanical genius to the improvement of the instruments used in lithotomy, and with a success which has disarmed this formidable operation of half its terrors to the surgeon, and greatly diminished its dangers to the patient, having constructed a staff and a knife, both of which are of great practical value.

Dr. N. R. Smith has succeeded with lithotripsy in five male children, one of whom was but one year and ten months old, which is the youngest child upon whom it has ever been performed. Dr. Randolph, of Philadelphia, was successful with the same operation on a little girl of four years of age, and a boy of thirteen.

Dr. Mott, of New-York, has performed the lateral operation of lithotomy in a great number of cases, and during an extensive practice of thirty-six years, has lost but four of his patients. He exclusively employs the bistoury for the prostatic section, and is wont to say in his lectures that he has never used a gorget on a living subject.

Dr. Parker, of New-York, has lately performed the high operation of lithotomy on an adult female with complete success. He was led to this method by the very large size of the stone, which forbade the hope of its extraction by Lisfranc's method of enlarging the urethra, and preferring, as he very properly did in such a case, the high operation to the vagino-vesical incision.

Dr. Mutter, of Philadelphia, reports, in the Amer. Journ. for 1837, a case of urinary calculus extracted from a girl of nine years old, by enlarging the urethra, the incision being made with a bistoury upward towards the pubis on a grooved staff, on the plan of Dubois, and which was attended with entire success. Dr. J. Rhea Barton, of the same city, has also practised this method with the like result, and in neither of these cases did any degree of incontinence of urine follow.

On this subject Mr. Cooper says, "Three or

four years ago I assisted Mr. Walne, of Bloomsbury Square, in extracting a calculus which was nearly an inch and a half in one of its diameters, from the bladder of a girl eight or ten years old. The meatus was first gradually dilated with Weiss's dilator: the incontinence of urine, following the operation, after a time subsided. I have also seen a piece of spermaceti candle, five inches long, and of the usual thickness, which had accidentally slipped into the bladder, taken out with the finger, after the meatus had been dilated for two or three hours with the same instrument; and in this case no incontinence of urine followed."

Dr. J. K. Rodgers operated on a female, and extracted a stone weighing 9 oz. and 5 drachms with complete success by a lateral incision, enlarging the urethra until it could be extracted. This is the largest ever extracted with success from the human bladder, and the patient recovered without incontinence of urine, or any other untoward symptom. Dr. Mott extracted a stone weighing 17 oz., which is the largest on record, but the patient failed to recover.—REESE.]

[LITHOTOMY BY THE RECTUM. Performed by Mr. Dawson, of the Liverpool Infirmary, on a little boy of three years and a half old. The case, a sacculated calculus, bulging downward, so as to be felt through the upper wall of the rectum. "A gum-lancet, having its anterior edge rounded and very keen, was laid flat on the finger, which, thus armed and oiled, was introduced through the anus so as to reach a point a short distance beyond the recto-vesical pouch, when its edge was turned upward, and a decided cut made by drawing the instrument from behind forward in the median line, through the walls of the pouch, and up to the stone, on the hard surface of which the edge of the lancet was distinctly felt to grate." After a second cut, the calculus was displaced by the finger, and fell into the rectum, whence it was withdrawn with Pellier's double silver wire. For four days urine was discharged from the rectum. On the tenth day, four ounces of urine passed in a full stream through the penis, and after this no urine was voided from the rectum. The child recovered favourably from the operation. (See *Trans. of Med. and Surgical Provincial Association*, vol. ii., p. 301. To the references at the end of the article LITHOTOMY, add *The Surgical Anatomy of the Perinæum, by Thomas Morton, late House Surgeon in the University College Hospital*, 8vo, Lond., 1838.)—C.]

[LOWER JAW, EXCISION OF THE ENTIRE. (Case by John G. Perry. The disease necrosis, with several sinuses opening around the chin.) One of these having been laid open, the entire case of new bone was found to be dead, and in a great measure separated from the periosteum. The removal of the bone was therefore determined upon. An incision was made along the basis of the jaw, from a short distance in front of the right masseter muscle to the corresponding point on the left side. The exposed bone was divided with a saw and cutting forceps, as near as possible to the angle of the wound, and the insulated portion removed. On the following day, the portion remaining on the right side, which had somewhat descended from the loss of the support of the central part, was removed without difficulty. At the end of three weeks the remaining segment was taken away. After the cure, the patient was able to masticate solid food with the aid of the tongue, which rubs the morsel against the upper teeth; but, as there is no reproduction of bone, the lower teeth are almost useless, and they do not meet the upper. (See *Med. Chir. Trans.*, vol. xxi., art. 17.)—C.]

[LUMBAR ABSCESS. The symptoms are commonly of the following kind: pain in the lumbar region, shooting to the groin and thigh, and stiffness and pain in the course of the spine, which symptoms are exasperated by extension of the thigh. The patient cannot stand well on the foot, and either limps in walking, or cannot walk without stooping. Any effort causes an increase of pain. Sometimes the inguinal glands are enlarged. According to Dr. Kyll, of Wesel, the disease admits of being discriminated from others, even in its earliest stage, by the following circumstances: the patient cannot walk in the upright position; he always leans a little forward; he can only straighten himself to a certain point, and he is stopped by a tearing pain, which is felt at the same instant in the groin and loins. The patient can go up stairs more easily than he can come down, because, in the latter movement, he is obliged to hold himself up. These symptoms are usually preceded for several weeks, or even months, by dull pain in the lumbar region.

Lumbar abscess may be mistaken for rheumatism, affections of the kidney, coxalgia, lumbago, hemorrhoidal pains, glandular swellings, and hernia. I have known the latter mistake frequently made when the abscess had formed a small swelling below Poupart's ligament. The points of difference are noticed in the article HERNIA.

I have attended several patients, each of whom had a double lumbar abscess. Two such cases were lately under me in University College Hospital, and ultimately recovered. In the same hospital we have seen patients whose thighs were drawn into complete contact with the belly from the effects of lumbar abscess; yet after the discharge of the matter, the limbs gradually resumed their proper position and use. The lumbar abscess is sometimes connected with diseased vertebræ, which may either be a cause or an effect of the collection of matter. The disease, however, is frequently unattended with this complication.

Chronic abscesses perpetually form in the loins without vertebral disease, and get well with ordinary care. (*Mayo, Outlines of Human Pathology*, p. 124.)

The practice of opening abscesses connected with the larger joints is considered by Dr. M'Dowel to be, in general, decidedly objectionable; but, says he, "when we consider the fatal consequences which may result from the unchecked progress of the deep iliac abscess, and take into the account the very great sufferings of the patient from pressure of the anterior crural nerve and its filaments, I believe this to be a case in which surgical interference is called for. The puncturing of this abscess, however, requires much caution. In superficial purulent collections in the iliac fossa, the peritoneum is detached, and pushed upward and inward sufficiently to permit the incision above Poupart's ligament being made with perfect safety: not so in the deep collections; there is then no separation of the peritoneum, and the opening must be made below Poupart's ligament, and, of course, with great caution." (See *M'Dowel, in Dublin Journ. of Med. Science*, vol. iv., p. 13.) Sir Astley Cooper's doctrine respecting the practice of opening abscesses connected with large joints, I have noticed in the article JOINTS, DISEASES OF THE.—C.]

M.

[MELANOSIS, derived from μελας, black, is a term employed to signify substances, occasionally developed in or upon the textures of the animal body, and characterized by their black colour.

Although references to melanosis of the lungs and liver may be traced in the writings of Bonetus, Morgagni, and Haller, the first very careful descriptions of the disease were given by MM. Dupuytren, Bayle, and Laennec. The name of *melanosis*, which was first adopted by Laennec, who published the earliest particular account of the disease (see *Bulletin de la Soc. de l'Ecole de Méd.* 1806. No. 2), is still generally retained. Professor Carswell uses the term *melanoma*. Our knowledge of the disease has been of late years much extended by the researches of Breschet, Trousseau, Leblanc, Carswell, and some eminent veterinary surgeons in France.

Under the title of *melanoma*, Dr. Carswell includes all melanotic formations, black discolorations, or products, described by Laennec and other authors; but, for the purpose of marking the difference in their nature, he arranges them in two groups; the first being distinguished by the appellation of *true melanosis*; the second by that of *spurious melanosis*. "Thus, (says he,) when these formations or products depend (as is the case with some of them) on a change taking place in that product of secretion, whence the natural colour of certain parts of the body is derived, or, in other words, when they constitute what is called an idiopathic disease, I shall consider them as belonging to the first group; and when, as in the case with others, (they originate in the accumulation of a carbonaceous substance introduced into the body from without, the action of chemical agents on the blood, or the stagnation of this fluid,) I shall include them in the second group. There are several black discolorations, which might also have been included in the present systematic arrangement, such as those observed in tissues affected with mortification, that have been subjected to the action of intense heat, or powerful escharotics of various kinds; but as they have never been confounded with any of the forms of melanosis, I shall not take any further notice of them in this place." Dr. Carswell then proceeds to describe, 1. *True melanosis*, of which there is only one kind. 2. *Spurious melanosis*, of which there are three kinds:—1. From the introduction of carbonaceous matter. 2. From the action of chemical agents on the blood; and 3. From stagnation of the blood. (See *Illustrations of the Elementary Forms of Disease, Fasc. on Melanoma.*) According to Dr. Carswell's definition, *true melanosis* consists in the formation of a morbid, unorganized product of secretion of a deep brown or black colour, and the form and consistence of which present considerable variety, solely in consequence of the influence of external agents.

Melanosis is more frequently observed in the cellular tissue than any other, and perhaps it is in consequence of that tissue entering into all the common structures and organs of the body, that melanosis is sometimes noticed in most of them. Thus, Andral describes examples of melanotic formations in a great number of the elementary tissues, where it may either exist singly, or in union with other organic disease. (See *Précis d'Anat. Pathol.* t. i. p. 459.) Melanotic productions may also be met with simultaneously in various textures and organs. M. Martin Solon relates the case of a woman, in whose right inguinal glands, thighs, and breasts, melanotic tumours had formed. (See *Dict. de Méd. et de Chir. Pratiques*, t. xi.) M. Alibert gives another case, where the skin, different regions of the cellular tissue, the mediastinum, the mesentery, omentum, many lymphatic glands, the thyroid gland, and the lungs, all contained melanotic deposites.

In the cellular tissue, the most frequent seat of true melanosis, the melanotic matter is formed after the manner of secretion, accumulates in the cells of that structure, and gradually acquires the form of tumours of various sizes. A similar mode of formation is still more conspicuous in loose cellular tissue, and particularly on the surfaces of serous membranes, like those of the pleura and peritoneum.

The next variety, noticed by Professor Carswell in the seat and mode of formation of melanotic matter, is that of its deposite in the substance or molecular structure of organs, after the manner of nutrition. Lastly, he adverts to the detection of melanotic matter in the blood, chiefly that contained in the venous capillaries, and under circumstances which prove, that it must have been formed in these vessels. (See *Illustrations of the Elem. Forms of Dis. Fasc. on Melanoma.*)

There are four varieties of true melanosis. (See *Andral, Précis d'Anat. Pathol.*, t. ii. p. 446.) The following names have been applied to them:—

1. The *punctiform* (melanose infiltrée) is that in which the melanotic matter presents itself in minute points or dots in the texture of an organ. It is principally noticed in the lungs and liver.

2. *Tuberiform* melanosis (concretions mélaniques, melanose en masse) is the most common variety of it, and is occasionally met with in most of the organs of the body, and sometimes on the surfaces of serous membranes. "In the former situation (says Dr. Carswell) the tumours are generally globular, and in the latter not unfrequently pyriform. They are most frequently found single in organs, and aggregated in cellular and adipous tissues, and have, perhaps, never been found limited to one organ, the deposition of the melanotic matter taking place simultaneously or successively in a great many organs, or in the cellular tissue of the different regions of the body. The melanotic tumours are most numerous in the cellular and adipous tissues, and from their aggregation produce lobulated or irregularly shaped masses of great bulk." Melanotic tumours are sometimes bounded by cysts, but more frequently have no cysts, (See *Andral, Anat. Pathol.*, t. i. p. 451,) but are in immediate contact with the texture in which they are produced. Laennec, indeed, divided melanosis into the encysted, and non-encysted. According to the researches of Dr. Carswell, melanosis is perhaps never found encysted in compound tissues, or organs, as the brain, lungs, liver, and kidneys; whereas it is always so in

the cellular and adipous tissues, and sometimes on the surface of serous membranes.

3. *Stratiform melanosis* (mélanose membraniforme) is represented by Dr. Carswell to be formed only on free surfaces, though M. Blandin states, that it is occasionally produced on the adherent surfaces of serous membranes. As the name leads us to understand, the melanotic matter is deposited in the form of strata, or layers, or of a pseudo-membrane. Its consistence generally resembles that of jelly, and is enclosed either in a soft spongy cellular tissue, or fine transparent serous membrane of new formation, so that, when pressed, it feels pulpy, but is not removed by the finger, or a scalpel passed over it, unless some force is employed.

4. *Liquiform, or fluid Melanosis*, was not described by Laennec, which, as Andral remarked, is not surprising, inasmuch as he regarded melanosis as a tissue or texture. M. Breschet has applied this name to certain liquids of a dark colour, which seemed to him to arise from morbid secretion. In some individuals, M. Andral found in the cavity of the abdomen, after chronic peritonitis, a black fluid which he regards as liquiform melanosis. Dr. Carswell remarks, that "the appearance of true melanosis in a liquid form has in general been confined to natural or accidental serous cavities. Among the former, the cavities of the pleura and peritoneum furnish almost the only examples in which the liquid melanotic matter has been observed, and that too in very small quantity. I have never seen it in man as a product of secretion, but have met with it in consequence of the destruction of melanotic tumours, and the effusion of their contents into serous cavities, the walls of which they had perforated. The accidental serous cavities, in which it has been found, are those which constitute cysts, particularly in the ovaries." MM. Trousseau and Le Blanc met with a fibrous cyst, as large as the fist, situated above the kidneys of a horse, and containing about eight ounces of black liquid.

Breschet, Andral, and Cruveilhier, in describing liquiform melanosis on mucous surfaces, especially that of the stomach, have confounded it with the black discoloration of effused blood, produced by the action of the gastric juice upon it.—(*Carswell.*)

The largest melanotic masses are found in the loose cellular tissue behind the peritoneum, and these are always composed of many smaller ones. The largest single tumours are noticed in the liver. In the horse, masses of true melanosis have been found in the former situation, weighing from twenty to forty pounds. (*Id.*) It is further explained by Dr. Carswell, that the consistence of true melanosis is determined by the texture and form of the part in which it is deposited. "Thus, it is never found solid in serous cavities, for the plain reason, that its diffusion is not limited by dense unyielding tissues. Even in tumours attached to the serous covering of these cavities, it is for the same reason either perfectly fluid, or not more dense than animal jelly. Loose cellular tissue is also occasionally filled with the black matter in a fluid state. In the dense texture of the cutis, on the contrary, even the smallest tumours may be as hard as cartilage, and are generally as firm as the pancreas. In the lymphatic glands, and in the brain, the melanotic tumour acquires only a medium degree of consistence, although it is generally firmer in the former than in the latter, in consequence of the capsule of the glands acting as a compressing cause.

Melanotic tumours are susceptible of a softening process, especially when situated near the surface. The skin becomes thin, ulcerates, and a fishy blackish matter, characterizing the disease, is discharged. This is what M. Blandin saw take place in an old woman, who was afterwards admitted into La Salpetrière, and whose case is recorded by M. Breschet. (See *Magendie, Journ. de Physiologie Experim.*, t. i. p. 354.)

Melanotic tumours, attacked by ulceration, or the knife, pour out blood as well as a blackish fluid. They may also throw out granulations, suppurate and heal, as was exemplified in the horse operated upon by M. Damoiseau, the particulars of which were published by M. Trousseau. (*Archives*, Juin, 1828, p. 180.) In ordinary cases, melanosis is not productive of much disorder in the economy. In the liver and the cellular tissue it may attain an enormous magnitude without giving rise, during life, to the slightest functional disturbance leading to the suspicion of its existence, provided it does not cause any mechanical oppression. When melanotic tumours exhibit any inflammatory action, or disposition to hemorrhage, it is the cellular tissue in their structure that is the seat of those changes, just as it is the seat of cancer which sometimes invades melanotic tumours. (*Blandin*, in *Dict. de Méd. et de Chir.*, t. xi. p. 392.)

Dr. Carswell and M. Andral differ from Laennec in believing the melanotic matter to be deposited first in a fluid state, and afterwards to acquire greater consistence from the cellular tissue in which it becomes enveloped. At an indefinite period of its formation, however, Dr. Carswell admits that the solid melanotic tumour loses its consistence, and softens; yet this change does not appear to him nor to M. Andral, as it did to Laennec, (*Précis d'Anat. Pathol.*, t. i. p. 450,) to be a vital process, originating in the melanotic matter itself, but to depend upon the destruction of tissues, which surround, or are contained in, the melanotic tumour, and upon the simultaneous effusion of serosity. Inflammation rarely accompanies the softening process, and, when ulceration and sloughing occur, they appear to be chiefly owing to the melanotic matter compressing or obliterating the blood-vessels of the tissues in which it is contained. (*Carswell, Op.* cit.)

The texture of the melanotic matter is homogeneous, void of smell, opaque, and a fluid exudes from it, which stains the fingers black; and it is not itself organized. In vain (says M. Andral) should we look for any trace of organization. It is merely a homogeneous substance, sometimes divided into lobules, or layers, by cellular tissue, which pervades it, without belonging to it. There are neither cavities, areolæ, nor fibres in it: no vessel, no nerve, is distributed in it. No characters exist entitling it to be called a texture.

As Professor Carswell observes, "when a number of melanotic tumours are grouped together, they are included in a common capsule, and separated from one another by their respective coverings and portions of cellular tissue, contained in the angular spaces sometimes left between them. It is in these filamentous and cellular tissues alone, that blood-vessels or nerves are to be seen. Minute arteries and veins may be observed ramifying in both, but they never pass beyond the limits of these tissues.

Large branches, and even trunks of arteries and veins are sometimes found passing over the surface, or included in the aggregated masses of melanotic tumours." (See *Carswell's Elem. Forms of Dis. Fasc. on Melanoma.*)

With respect to the chemical composition of melanosis, M. Thenard detected carbon in it; M. Clarion, albumen and a peculiar black colouring matter; and M. Barruel ascertained, that this last is analogous to the colouring matter of the blood. He also made out the presence of a particular modification of fibrine in it, and the existence of phosphate of iron in it; elementary ingredients also in the blood. M. Foy made a comparative analysis of medullary or encephaloid, scirrhous, and melanotic formations, and he detected in these different substances albumen, fibrine, and salts, the basis of which were soda, potassa, lime, and oxyde of iron, in rather less proportion in the two first formations than in melanosis; and in this latter a highly carbonized principle, composing nearly one third of it. Those various researches thus all tend to prove a close analogy between the elements of melanosis and those of the blood.

Melanosis is not restricted to man. It is more frequently noticed in white and gray horses than in those of any other colour; MM. Rodet and Breschet have met with it also in horses of a light bay colour; and dogs, cats, rabbits, mice, and rats, are all subject to it. In horses, melanotic swellings form especially under the tail, and thence extend to a greater or lesser distance within the pelvis. They may often be removed from this situation with success.

Though melanosis may occur at any period of life, and even in the fœtus, as a melanotic formation on the cerebellum exemplified in a preparation in University College Museum would tend to prove, yet it is more common in adults and aged persons than very young individuals.

Melanosis was regarded by Laennec as a species of cancer. (*Auscult.*, t. ii. p. 33.) But in its appearance and progress, it is very different from the latter. The white resplendent hue and the lardaceous texture of scirrhus, which yields a grating noise as the knife passes through it, present no resemblance to melanosis. The lancinating pains of cancer; the characters of the encephaloid tumour; the tendency of these formations to be reproduced after having been extirpated; the hectic fever and other derangements of the health to which they give rise; are circumstances sufficiently marking the differences between melanosis and cancer. The only examples likely to have occasioned such mistake, are those in which melanosis and cancer are united together. The same remark applies to tubercular disease. The *carcine mélanée* of Alibert, and the *cancer anthracine* of Jurine, seem to have differed from simple melanosis in their tendency to be reproduced in other parts after extirpation, and in their disposition to soften and be accompanied by ulceration, and all the evils peculiar to cancerous diseases. At all events, then, it would seem as if there are modifications of melanosis, which are of malignant character, whether we adopt the doctrine or not, that they are combinations of cancer and melanosis together.

The fact of melanosis taking place chiefly in white, gray, or light bay horses, is a curious one, seeming to prove that the black matter of this accidental production is deposited in internal organs, as it were, in consequence of such colouring matter not being secreted by the skin. Perhaps, however, as M. Andral observes, there has been too much disposition to generalize on this point; for M. Rodet has published instances of melanosis in horses of all colours. (See *Anat. Pathol.*, t. i. p. 475; and *Rodet*, in *Journ. de Méd. Vétérinaire, par M. Dupuy*, t. ii. p. 273.)

Simple melanosis is not of itself dangerous: it causes no particular disturbance of the health, unless from its size it happen to press upon organs and produce functional disturbance. It may also be combined with cancer, or it may be attended with inflammation and ulceration of the texture, directly connected with it. By its pressure on important vessels, it may also give rise to dropsy.

Surgery possesses no means of dispersing a melanotic tumour, the only plan of cure being that of removing the new production with a knife. The practicableness and propriety of this will depend upon the situation and extent of the disease, and the inconveniences experienced from it.—C.]

[MYOTOMY. The honour of being the first surgeon in America, who performed myotomy, as it may be contradistinguished from tenotomy, for the removal of deformity in a limb, belongs to Professor Paul F. Eve, of Augusta, Geo. The case will be found reported in the *South Med. and Surg. Jour.*, for 1838; and consisted in the successful division of the Adductor Longus Femoris, for deformity and consequent loss of motion in the thigh. The incision was made along the internal edge of the muscle, commencing at the pubis, and extending in a similar direction five inches, and the muscle was then divided about three inches below its origin from the pubis. For the details and subsequent treatment, I have no space, but the success of the operation was complete. (See TENOTOMY, WRY NECK, &c., in the Appendix.)

In Europe the division of the muscles has been practised of late for the reduction of long standing dislocations, and for removing distortions of the spine. The trapezius, rhomboides, levator anguli scapulæ, sacro lumbalis, and longissimus dorsi, have been subjected to myotomy. Some of these sections have been made in America, prompted by the success of M. Guerin, of Paris, but I am not informed of the results. Dr. Flint, of Louisville, in his Notes on Druitt's *Vade Mecum*, lately reprinted by Lea and Blanchard, of Philadelphia, severely censures these barbarous operations, and applies to these Mr. D.'s own epithet, in reference to the myotomy employed in cases of stammering, which he denominates, "muscle-cutting-gone-mad."

Dr. Mutter, of Philadelphia, has lately divided the adductor and the pectineus muscles in a lady, who for nine years had been deformed and crippled by their permanent contraction. The operation has been successful, and the lady is enabled to walk without crutches.

Dr. J. W. Schmidt, of New York, has cured a case of immobility of the lower jaw, by the subcutaneous division of the masseter muscle, after the instrument employed by Dr. Mott, for opening the mouth in analogous cases, had been repeatedly used without success. The case was one which was dependant upon a contraction and rigidity of *one* of the masseters, consequential upon ulcerated sore throat, and had existed for twelve years. Dr. Carmochan, of this city, performed a similar operation, but a true anchylosis of the joint prevented its success.—REESE.]

N.

[NECROSIS. Dr. Alex. E. Hosack has a paper in the *Amer. Journal of Med. Sciences*, for 1831, on the application of the actual cautery in various diseases, from which it appears, that in the forming state of necrosis, and when matter is established under the periosteum, so as to denude it, this surgeon adopts the practice of laying open the tumour so as to completely expose the bone, or so much of it as is involved, and then applying the actual cautery at a white heat, searing the surface thus exposed. Dr. Hosack has treated several cases in this way with entire success.—REESE.]

[NEURALGIA. Dr. J. C. Warren has had considerable experience in the treatment of neuralgia, and reports as follows:

Supra-orbitary nerve divided in two cases with success; the infra-orbitary nerve divided fifteen times, and in six cases it succeeded; the facial nerve divided twice without success; and once the inferior maxillary nerve, which removed the disease.—REESE.]

[NEUROMA, or Neurotic Tumours. Professor Parker, of New York, has distinguished three varieties.

1st. A very small tumour in or directly under the skin, and seeming to occupy the very extremities of the nervous filaments. They are very painful, especially if touched or handled, and require excision.

2d. Occupying the trunk of a large nerve. He has lately removed one from the ulnar nerve, just above the internal condyle, which had attained the size of a pullet's egg, having subsisted for several years. It was attributed to repeated blows received upon the nerve where it passes over the olecranon. None of the original filaments could be traced in the tumour or upon its surface, having changed into a pulpy mass, contained within the thickened and distended neurolema.

3d. This variety is found upon the end of stumps, and is the source of the acute pain sometimes so afflicting after amputation.

Mr. Cooper's article on this subject is entirely new, and is worthy of attention.—REESE.]

Neuroma, (from *νεῦρον*, a nerve,) a term originally employed by Odier to signify a tumour formed in or upon a nervous trunk. This subject has been ably investigated by Mr. Wood, the results of whose researches are published in the *Edinb. Med. Chir. Trans.*, vol. iii. part 2. Tumours, connected with nerves, are subject to much variety. Sometimes, though rarely, the swelling consists almost entirely of a cyst, filled with a fluid, as exemplified in the case operated upon, and reported by Cheselden. In other instances, it is in part solid, and in part fluid: more frequently it is solid throughout. In one of the cases detailed by Mr. Wood, the tumour consisted almost entirely of a firm membranous cyst, containing a thick fluid; in three others, it consisted partly of fluid, and partly of a solid substance; and, in twenty, it was entirely of a solid texture. The consistence, colour, and appearance of the solid part differ in different cases; and sometimes in different parts of the same tumour. In some instances, the whole mass is very firm and hard, of a whitish, or yellowish colour, and of a fibro-cartilaginous appearance, harder than a nerve, and rather more shining. The fibres run generally in a longitudinal direction, but are not always parallel, and the interstices of them were observed by Mr. Wood to be filled up by the substance of the tumour. In other cases, one part of the mass is solid, of a reddish colour, and steatomatous appearance; and, in another part, there are cells of a larger or smaller size, some empty, others containing either fluid, or a softish medullary substance. Occasionally small lobes are met with, all distinct, but closely pressed together. In almost all cases, Mr. Wood observed a firm sac, more or less dense, and of a shining appearance, not unlike tendon, and seemingly formed in part or entirely of diseased neurilema. In some cases, the sac is loosely attached to the contained parts by a thin cellular substance; in others, it is firmly incorporated with them; and sometimes it is attached to, or partially covered with muscular fibres. The nerve itself is sometimes sound where it enters and comes out of the tumour; but more frequently it is thickened, and now and then reddened. The nerve may often be traced to the surface of the diseased part, and some of its fasciculi even into the substance, or sac of the tumour. When, however, the swelling is very large, none of the nervous fibres can be traced from the trunk above to that below the tumour. The circumstance of the disease affecting only a certain number of the fibres of the nerve, seems to Mr. Wood to account for the complete power of sensation and motion, often retained in the limb beyond the tumour. That part of the nerve does continue adequate to its functions, when another part of it is much diseased, is proved by the effect of dividing the nervous trunk in the operation for the removal of the tumour, when the sensation and power of motion, which had previously been little impaired, became instantly destroyed, or much diminished. (See *Wood*, in *Edinb. Med. Chir. Trans.*, vol. iii.)

The pressure of a neuroma may give rise to local pain and numbness, and, in some instances, it has been known to occasion convulsions and epilepsy. In a case recorded by Portal, a woman was freed from epileptic attacks by the removal of a tumour, which had formed on one of the nerves of the thumb.

The generality of neuromatous swellings do not seem to be of a cancerous nature; "first, because however large the diseased mass is, or however long it may have existed, the contiguous textures, and more particularly the skin, do not become affected with disease of a maliguant kind; and, secondly, because there seems to be no tendency to a return of the complaint after it has once been removed by operation." (*Wood, ib.*)

We know from the history of medullary cancer, however, and especially from the history of this disease, as it presents itself in the eye, that the nerves may be the seat of it. Now and then a neuroma is met with exhibiting a brainlike and bloody substance. Mr. Liston removed from a middle-aged and healthy-looking man a tumour, which had occupied the popliteal space for a considerable period. It was growing rapidly, had attained the size of a cricket-ball, and was seriously impeding the motions of the limb. On the

dissection, the tibial nerve was found intimately connected with it, the fibrillæ stretched over its sheath entering into, and being mixed with the substance of the growth. The nerve was cut above and below, and the whole mass extirpated, broken, and entire. During the stay of the man in the hospital, a tumour was detected on the front of the thigh of the same limb; here an inflammatory swelling took place, and suppurated. It was opened, but the original lump did not disperse. Within six months after the healing of the wound in the ham, the patient returned with an enormously swollen limb, and a large elastic morbid mass in the back part of it. A bleeding fungus protruded; and the disease was soon fatal. The original tumour, now in Mr. Liston's collection, is soft and bloody; but that on the fore-part of the thigh was fibrinous, ovoid, larger than a hen's egg, and involved the anterior crural nerve. The diseased structure, which had been reproduced in the popliteal space, had all the characters of fungus hæmatodes. It seems extraordinary, that, in this case, the removal of the tumour from the ham, with at least three inches of the tibial nerve, should not have been followed for an instant by any loss of power of motion or sensation in the limb or foot. (See *Liston on Pract. Surgery*, p. 294.)

The following advice in relation to the treatment, as offered by Mr. Mayo, appears good. The tumour should be exposed, and if separable from the surface of the nerve should be removed, whether solid, or a cyst. If completely implicated with the whole structure of the nerve, and that nerve a small one, it should be removed with the portion of nerve involved with it. "If so implicated, and *the nerve the sciatic*, and the tumour a cyst, the cyst might be punctured, and the fluid evacuated, every precaution being taken to unite the wound by adhesion. In the last case, supposing the tumour to prove solid, another question might still arise; whether, the nerve being first divided above the tumour, the latter would not admit of being dissected out of so palsied a limb, with more probability of safety to the patient, than if the nerve to be operated upon were left in communication with the brain." (See *Mayo's Human Pathology*, p. 146.)

An interesting account of the removal of a tumour of the radio-spiral nerve of the right arm has been published by Dr. Gibbs. The case terminated successfully, with a recovery of some slight use of the extensor muscles of the fingers; and "the patient was dismissed with returning sensation in the back of the hand, and a tolerably free use of the arm." (See *Edinb. Med. and Surg. Jour.*, vol. xxxiii. p. 250.)

As is well known, when nerves have been divided in amputation, their extremities swell into firm bulbs of an oval shape, and frequently of the size of a nut. In certain instances, these enlargements of the ends of nerves cause most severe neuralgic sufferings, and this probably, as Mr. Lawrence conceives, either from the bulbous swellings of the nerves being involved in the cicatrix, or pressed by the contraction of it against the sawn end of the bone. (See *Langstaff*, in *Med. Chir. Trans.*, vol. xvi. p. 155.) For additional remarks on this last subject, see STUMP. For engravings of the appearances of the ends of nerves in stumps, consult *P. G. Van Hoorn deiis quæ in partibus Membri præsertim osseis amputatione vulneratis, notanda sunt.* Lugd. Batav., 1803, 4to.—C.]

[NIPPLES. In addition to what is stated upon the subject of sore nipples in the article MAMMA, I may observe, that the nitrate of silver is an excellent application for the cure of this painful and sometimes obstinate complaint. Dr. Hannay, of Glasgow, strongly recommends its use in the following manner. Having gently, but carefully dried the nipple, the part is to be freely touched with a sharp pencil of nitrate of silver, which is to be insinuated also into the chaps and chinks. The nipple is then to be washed with a little warm milk and water. The pain soon subsides, and the sore may then be healed with a little zinc ointment. Dr. Hannay occasionally washes the nipple with a saturated solution of borax before and after suckling the infant. (See *Lond. Med. Gaz.*, vol. xiv. p. 674.) Sir Astley Cooper's formula of borax for these cases is specified in the article MAMMA. Dr. Jewel adds his testimony in favour of nitrate of silver. (Op. et vol. cit. p. 753.) Pyroligneous acid, blended with white of egg, is another remedy sometimes preferred. (*Gaz. Medicale.*) —C.]

[NŒVI MATERNI. Dr. J. Rhea Barton, of Philadelphia, has for a number of years practised an operation for these deformities, when aneurismal, by inserting two pins at right angles through the base of the tumour, and then encircling these with a ligature. The pins form four fixed points, beneath which the ligature may be tightly drawn, and a neck is thus formed even upon those flattened bodies. Some of the British surgeons have adopted a similar practice, but as Dr. Barton used it in Philadelphia simultaneously with the intelligence that a similar operation was performed in England, I am unable to decide the claim of priority, though it was original on the part of Dr. Barton, he having devised and executed it before he had ever heard of its being elsewhere thought of. His success has been very gratifying in numerous cases.

Dr. J. C. Warren has had extensive experience in the removal of these affections, having removed three by caustic, eight by ligature, and eighty-five by excision, all of them successful; although in one case he found it necessary to practise excision twice. See his splendid work on Tumours, for interesting cases of aneurism by anastomoses.

Dr. A. H. Stevens prefers a peculiar form of seton for the removal of nœvi of the aneurismal variety. He passes an armed needle longitudinally through the tumour, having attached to the extremity of the thread a thickened ligature, composed of threads folded together until their bulk is sufficient to plug up both the openings made by the entrance and exit of the needle. In this way he avoids all hemorrhage, by drawing the needle through quickly, including the thickened ligature, and leaving the latter. Inflammation and suppuration take place within the cavity transfixed by the seton, and obliterate it completely. I have seen this eminent surgeon remove such deformities from the face, in positions to which neither of Dr. Warren's methods were adapted, and either of them, if successful, must have sadly disfigured by the operation, while this method leaves scarcely any trace of the operation.

Dr. Mott prefers, in all these cases, the employment of acupuncturation with needles, heated to a white heat by the flame of a spirit lamp, a practice introduced by the late Dr. Bushe. He passes these hot needles directly

through these aneurismal tumours, some eight or ten times in different and opposite directions. Not a drop of blood flows, the pain is very inconsiderable, and I have had the opportunity of witnessing his success in repeated instances. The effect of this acupuncturation upon the tumour is like the seton, and leaves scarcely any scar.

Dr. John Watson, of New York, has published in the *American Journal*, for 1839, a critical paper on the nature and treatment of Telangiectasis, or that morbid state of the blood-vessels which gives rise to nœvus and aneurism om anastomosis. This barbarous specimen of technology was introduced originally by Graefe, as a synonyme for the nœvus maternus of the older writers; the aneurism from anastomosis of John Bell; the tumeur variqueuse or fongueuse sanguine of Boyer; and the tumeur erectile of Dupuytren. My limits will only permit me to refer to this valuable article of Dr. Watson, which abounds with discriminating good sense and practical information on this obscure and difficult topic.—Reese.]

[NOSE, HYPERTROPHY, or LIPOMA OF THE. The growth, or enlargement, seems to be restricted to the skin and subjacent cellular tissue. These textures become thickened; and "the sebaceous crypts are enlarged and distended with their secretion, some of them to a considerable degree, and forming encysted tumours of the size of a garden pea; the cellular tissue is loaded with serosity, and, in some places, there is fibrinous deposite. The arterial capillaries are not much enlarged; but, when the part is dependant, or the circulation much excited, or the return of blood prevented by violent exertion of the lungs, the veins are much enlarged, giving the tumour a more blue and distended appearance. Different parts become affected in succession, and the mass is made up of many growths from the point and sides, of various sizes, separated by fissures, in which the sebaceous secretion, often rancid and offensive, lodges. These swellings, though attached by pretty broad bases, are loose and pendulous." (See *Liston on Pract. Surgery*, p. 237.)

In some instances, the tumour has been known to extend over the mouth and nostrils so much, that the patient could not breathe well, especially during sleep, unless a tin tube was placed in one of the nostrils. If the tumour were not supported with the hand, it also became immersed in any liquid that was brought towards the mouth to be drunk. (See *Hey's Surgery*, ed. 2, p. 565.)

In one of the cases, under this last practitioner, the case appeared to be nothing more than an enlargement of the common integuments of the nose. The bones and cartilages seemed to be in their natural state. For, though the latter were buried in the mass, yet, when the tumour was supported, Mr. Hey could distinctly trace, with his finger, the border of the cartilages. The tumour was divided in the middle; and, at the origin of this cleft, he could discern a small portion of the tip of the nose. The sebaceous cryptæ were so much enlarged, that some of them would admit the end of a crow's quill. Mr. Hey operated as follows:—having felt, with his finger, the border of the cartilaginous part, which gives the nose its proper figure, he marked out this border upon the inferior surface of the tumour, with a pencil moistened with Indian ink. Then, allowing for the thickness of the cartilage, and a proper covering of adipose membrane, he made his first incision parallel to the line marked out. He next pursued the dissection upwards, aiming at preserving the natural figure of the nose. When the principal mass had been removed, he reduced the remaining part of the adipous substance to an even surface by means of the tonsil scissors The hemorrhage, which was considerable, was stopped during the operation by the pressure of the fingers of the assistants. The patient, though a stout man, nearly fainted from the loss of blood; but, after the completion of the operation, the bleeding did not return. The case succeeded perfectly.

I have seen the operation performed in one or two instances by Mr. Liston. The following is the method preferred by him. "An incision should be made through the diseased integument and cellular tissue in the mesial line upon the cartilage of the apex and columna, not however so as quite to reach them. An assistant places his forefinger in one nostril, and the surgeon, seizing the mass with his fingers, or with a small volsellum, proceeds to dissect it off with a scalpel. The incisions must be carried pretty close to the cartilages of the ala, until the one side is cleared, the edge of the opening being well observed, and neither that, nor the cavity encroached upon. The assistant will give warning, if the knife, at any stage of the proceeding, approaches his finger. The surface is trimmed a little, if occasion requires, with a pair of thin slightly curved, or knife-edged scissors. A similar proceeding is observed on the opposite side, and they (the two sides) are to be made as symmetrical as possible. A few vessels may bleed: but the bleeding is easily restrained during the dissection, by placing the small spring forceps (Graefe's) upon their mouths, or they are compressed by the point of the finger. Ligatures are afterwards placed upon them if they still persist in bleeding. Should the ligatures not hold, the cut ends (of the vessel) not being readily drawn out from the condensed tissue, a fine cambric needle may be passed across the bleeding point, and a ligature tied under it, the ends of both the needle and thread being cut off. Any troublesome general oozing may be stopped by plugging the anterior nares, applying a compress of lint, and a double-headed roller. Difficulty and pain are experienced in removing this dressing, and it is much better, if possible, to apply frequently and assiduously for a few hours, pledgets of lint, moistened with cold water, and after coloured discharge has ceased, to substitute the tepid dressing, and thus encourage suppuration as speedily as possible." The exposed surface having granulated, the zinc lotion may be used. Mr. Liston has removed many of these growths without any untoward accident. In only a single case, a repetition of the operation became necessary after an interval of nine or ten years. A tumour of large size had been removed from the apex of the nose, leaving the integuments of the alæ slightly thickened. These afterwards increased so as to form a bulky swelling on each side of the apex. (See *Liston's Practical Surgery*, p. 240.)

See also *Civadier*, in *Mém. de l' Acad. de Chir.*, t. iii. p. 511. *Imbert Delonnes, New Progress of Surgery in France; translated by T. Chavernac.* 4to, Lond. 1801.

Nose, Hemorrhage from. Epistaxis. In consequence of the bleeding being sometimes profuse, and incapable of being stopped by other means, it becomes necessary to plug up the nostril

and corresponding posterior opening of the nasal fossa. A loop of wire, or a bougie, may be introduced along the floor of the nostril from before, backwards; and when it reaches the pharynx, it may be taken hold of with a pair of forceps, and brought forwards in the mouth, so as to allow a strong ligature to be attached to it, which is next drawn into the nasal fossa, and out of the nostril, by means of the wire, or bougie. This now becomes useless, and may be cut off. To the middle of the ligature, a dossil of lint is fastened, and the ligature being then drawn more out of the nostril, fixes the lint in the posterior aperture of the nares. The nostril itself is then to be closed with a plug of lint. The dossil of lint may easily be removed from the posterior opening, when no longer required, by displacing it with a probe introduced through the nostril, and the aid of the portion of the ligature in the mouth. This part of the ligature should be kept against the roof of the mouth, by fastening it to the upper lip with a piece of adhesive plaster. A still more simple mode is to use a loop of catgut, which will pass to the back of the fauces as readily as wire, or a bougie, and one portion of it being then drawn forwards out of the mouth, will serve for the conveyance of the plug of lint to the posterior opening of the nasal fossa.

Nose, *Operation for the Restoration of.* The Tagliacotian method, which consisted in employing a portion of the integuments of the fore-arm for the purpose, is now superseded by the oriental plan, in which the cicatrized remains of the former nose are converted into fresh-cut surfaces, and a flap of skin, duly shaped, is twisted, and brought down from the forehead, so as to admit of being united to them. This is the *rhinoplastic* art, as it is termed, from *ῥὶν*, the nose, and *πλάττειν*, to form, which has been practised in India time immemorial, and for many centuries in Italy, where cutting off the nose was a common punishment for certain offences, even as long ago as the period of the ancient Romans. The following is the mode adopted by Mr. Liston:—"A piece of soft leather, cut to the shape and size of the integument required to replace the apex and alæ, is placed flat upon the forehead. To secure accuracy in the line of incision, its boundaries are marked on the skin with ink, in case the patient prove unsteady. The flap being thus defined, is dissected down, and kept of uniform thickness, till near the lower angle, when the incisions should be carried deeply, so as to ensure an abundant vascular supply. Care should be taken, however, to avoid the periosteum, for otherwise exfoliation may follow, which would increase the scar, and render the cure tedious. This narrow part of the flap, or attachment at the root of the nose, must be of some length, to allow of its being twisted, so as to bring the integument to the exterior, when the part is adapted to its new situation; and to facilitate this, the knife should be carried a little lower down on that side on which it is intended to make the turn. After the bleeding has ceased, the flap is retained in apposition with the raw edges of the truncated organ, by points of suture. A little oiled lint is placed in the nostrils to support the flap, but no other dressing should be applied. The surgeon should be in no hurry to fix the flap; for union is most likely to occur when bleeding has ceased, and the edges of the wounds have begun to assume the glazed appearance, which precedes secretion. The lower part of the wound in the forehead is brought together by suture. To the rest, lint moistened with warm water, and covered with oiled silk, is applied, the lint being rewetted from time to time." As for the nose itself, the lint may be removed in three or four days, and then too perhaps some of the stitches may be dispensed with. The flap will be found adherent, yet moveable with the breath. During the cure, contraction of the nostrils is prevented with tubes. When the nose is firmly consolidated, and a collateral circulation has been established, so as to become independent of the supply of blood through the twisted attachment, this is to be divided with a bistoury, so as to remove a wedge-like portion, and let the front of it be laid down smoothly over the root of the nose. With respect to the columna, the practice in India was to obtain this by taking a slip from the forehead, along with the rest of the flap; but Mr. Liston has found it much better first to form the main portion of the nose, as already described; and, after this has become consolidated, to raise a columna from the upper lip. The inner surface of the apex is first pared. A sharp-pointed bistoury is then passed through the upper lip, previously stretched and raised by an assistant, close to the remains of the former columna. The incision is continued down to the free margin of the lip; and a similar one, parallel to the former, is made on the opposite side of the central line, so as to make a flap about a quarter of an inch in breadth. The frænulum is then divided, and the prolabium of the flap removed. The new columna is then fixed in its proper place with a sewing needle, which after its head has been covered with sealing-wax, to facilitate its introduction, is passed from without through the apex of the nose, and obliquely through the extremity of the elevated flap. Then a few turns of thread suffice to keep the fresh-cut surfaces in contact. Twisting the flap is here unnecessary. Lastly, the edges of the wound in the lip are to be brought together with the twisted suture. (See Harelip and *Liston's Practical Surgery*, p. 213.)

O.

[OPHTHALMIA. Professor Dugas, of Geo., has a paper in the South. Med. and Surg. Jour. for 1836, on purulent ophthalmia, which relates several cases, all of which were successfully treated by a solution of chloride of soda as a wash, one half an ounce to a quart of water. He was led to employ it, by reflecting upon the anti-suppurative properties of the article, which are so well known to every practitioner.

Dr. Isaac Parish, of Philadelphia, has published in the Med. Exam. for April 16th, 1842, a paper on the iodide of potassium in ophthalmic diseases. The dose he recommends is from two to six grains, three times a day, in a table-spoon-

ful of the compound sirup of sarsaparilla. It is said to possess great potency in relieving the acute neuralgic pain in the eyes, temples, and head, which are often present in inflammatory affections, involving the deep tunics of the eye. In granular conjunctivitis, sclerotitis, iritis, and strumous inflammation it proved successful.—REESE.]

[ORTHOPÆDIC. This new surgical speciality, though so lately introduced, seems to promise the successful removal of nearly all the deformities of the human body, however extensive or complicated, and whether morbid or congenital. Under the several articles on Clubfoot, Strabismus, Wry-neck, Tenotomy, Myotomy, &c., it will be seen that American surgeons have been diligently occupied in this novel department of surgery, and with a boldness and success which will compare with the achievements of any of their transatlantic contemporaries. I must refer to these several articles for the operations, improvements, and success, which have crowned their exertions, so far as they have reached me. Among those who have cultivated this branch in America, I may name Drs. Mott, Detmold, Parker, Mutter, Pattison, Dixon, Eve, Gross, Post, Smith, Davenport, Walter, Dix, and many others.—REESE.]

[OSTEOSARCOMA. Under the head of Tumours, Exsection of Bones, Jaw-bone, and Amputation, a number of cases of this disease are related, removed by operation, and among these Dr. Mott's exsection of the clavicle in 1828, and the lower jaw in 1821; Dr. Stevens' operation on the upper jaw in 1823, and extirpation of the astragalus in 1826. Dr. Muzzey's removal of the scapula and clavicle together in 1837, and the repetition of this last operation by Dr. M'Clellan, are worthy of notice.—REESE.]

[OVARY. This organ may be converted, 1. into a single cyst, which will sometimes acquire such magnitude as to fill the whole of the abdomen, and to cause a swelling resembling that of ascites. Cruveilhier deems it probable, that in this case the enlargement of one vesicle of the ovary has obliterated the rest of this organ, which is found to be in the state of atrophy at some point of the circumference of the cyst, and confounded with cartilaginous and osseous deposites. 2. There may be a single pouch, as in the foregoing instance, but from its inner surface arise nipple-shaped growths of various dimensions, composed of a substance having the consistence of the vitreous humour, or of that of the crystalline lens, and contained in irregular fibrous cells. In the first example the fluid in the cyst is mostly limpid; in the second, viscid like white of an egg, or tremulous as jelly, and incapable of being discharged by puncture. 3. The tumour may be divided into a multitude of cells, or pouches, filled by matters of diversified kinds, as limpid serum, a viscid albuminous fluid, a reddish gelatinous or a bloody purulent fluid. Cruveilhier has found many of these cysts filled with a cretaceous substance. Andral, in noticing the accidental formation of mucous textures, informs us that he has met with some ovarial cysts, the structure of which was more like that of a mucous than a serous membrane; and Meckel makes a similar remark. (See *Andral, Anat. Pathol.*, t. vi. p. 264.) It is not unusual to find one, two, or three of the cysts, forming a half, two thirds, or three fourths of the swelling. The cysts may be perfectly distinct from one another, or in groups, with communications between them. 4. Acephalo-cysts. 5. Cysts, containing hairs and an atheromatous substance. 6. Ovarial cysts, containing a fœtus, or portions of it. Mr. Williams, of Denbigh, lately informed me of an ovarial abscess from which he removed a full grown tooth. Under Mr. Gunning, in St. George's, and also under Dr. Blick, of Walthamstow, I have seen cases in which the bones of fœtal subjects were extracted from similar abscesses. 7. Cysts, resting upon a cancerous base. (See *Cruveilhier, Anat. Pathol.*, t. vii. livr. 5me.)

This author relates the particulars of a case where an ovary transformed into many pouches, all filled with a gelatinous substance, was mistaken for ascites, and punctured in vain. An encysted dropsy of the ovary in its early stage is easily distinguished from ascites. The circumscribed form of the cyst is the pathognomonic character of it, wherever situated. As for the development of the cyst on one side of the abdomen—a circumstance generally specified as a test—Cruveilhier regards it as theoretical and deceitful, because the cyst, as it increases in size, extends towards the central line, where there is the least resistance. But, when the cyst fills the whole of the abdomen, the criterion of its circumscribed form can no longer be adopted. Then the disease will not admit of being discriminated from ascites, either by the size or shape of the abdomen. The following considerations will here throw light on the diagnosis: Ascites is seldom an idiopathic affection, being generally dependant upon organic disease of the abdominal viscera, or connected with peritonitis, whereas ovarial dropsy is almost always a local disorder, frequently existing while all the other organs are healthy. In ascites the fluid always gravitates to the lowest situation: hence, when the patient is lying down, the fluid descends towards the pelvis and lumbar region. The small intestines lie, as Frank has explained, in the umbilical region, the arch of the colon, and the stomach in the epigastrium. Tap the belly gently with the finger, or with the ivory plate of M. Piorry, and the sound will be flat in the hypogastrium and loins; and the flat or dull sound will change its place according to the varying situation of the fluid in the different positions of the patient; but the sound will always be hollow in the umbilical and epigastric regions. On the contrary, in encysted dropsy of the ovary, the cyst is developed in front of the bowels, so that the gaseous sound can never be perceived in front of them; an observation first made by M. Rostan. The fluctuation is never so distinct in ovarial dropsy as in ascites, but of a duller kind. In ascites the neck of the womb remains in its natural place. In ovarial cases the uterus is not propelled down, as usually stated, but displaced upwards; and in this case, the cavity of the pelvis is filled with a tumour which is an appendage of the abdominal swelling. Ascites rarely exists without visceral disease and anasarca of the lower extremities, a symptom frequently absent in ovarial cases.

When the ovary is transformed into several cysts, the fluctuation is generally obscure; but in many cases, the bulgings of the tumour may be discerned, either through the parietes of the abdomen, or through the vagina, or rectum. Cruveilhier advocates the excellent general maxim never to make a puncture unless the fluctuation be very distinct. A puncture, he thinks, can only be of service when there is one cyst of serous

fluid. "The distinctions (he adds) of single and multiplied cysts would be very important if the extirpation of the ovary were to become an approved operation. The latter should not be meddled with; the former alone admitting of extirpation when their contents have been discharged, and a moderate incision is made in the parietes of the abdomen." See *Cruveilhier*, vol. cit. livr. 5me.)

Ovarial cysts and tumours are exceedingly common; and are often met with in young and middle-aged women, both single and married. Dr. Barlow gives an instance in which each ovary was found converted into ten or twelve cysts in a girl only ten or twelve years of age. (See *Prov. Med. Trans.*, vol. iv. p. 434.) The rate at which the disease advances, varies in different cases. Sometimes it does not attain a very large size till some years have elapsed; in other instances its augmentation is rapid: in the latter circumstances, the irritation is usually considerable. A patient under me at the Bloomsbury Dispensary, whom I used formerly to tap about once every two months, has remained with the disease in nearly a stationary condition for the last five years, having become tired of repeated operations. I have generally found, that the danger is more in relation to the quality of the fluid than the size of the swelling. If thick, dark-coloured, and very glutinous, paracentesis only affords temporary relief; and the repetition of it is sooner or later followed by inflammation within the cyst, and fatal disturbance.

The growth of some ovarial tumours, if in their early stage, and, as Dr. Barlow thinks, while the organic transformation of the part has not advanced too far, seems sometimes to admit of being checked. Nay, as some cases reported by this gentleman prove, ovarial dropsy is not always absolutely incurable. The means which he found most useful were moderate local or general bleedings whenever pain and irritation came on; blisters, or issues; belladonna plasters, digitalis, and iodine. In some cases, I have prescribed the hydriodate of potash, but never with decided success. I have often known the pain and irritation relieved by cupping, blisters, purgatives, and the preparations of morphia.

Under the head of *Paracentesis*, I will notice the operative expedients for the relief or cure of ovarial dropsy.

On ovarial cysts, which are most commonly, but not always, of the kind called fibrous, Delpech offers many cases, accompanied by observations. (See *Chirurgie Clinique*, t. ii. 4to, 1828.) In one of his dissections, a sero-mucous and a horny cyst were both found connected with the ovary; a case which he deems exceedingly rare. He affirms that the cure of an ovarial cyst has never been observed, whether as the work of nature or art; and nothing can be cited that would justify any comparison with the spontaneous or artificial terminations of the sero-mucous and horny cysts. From the cases and dissections of ovarial cysts which he records, he deduces, amongst other inferences, the following:—1. They are the product of a particular and accidental organization, and by no means of the gradual dilatation of the natural vesicles of the ovary. 2. Observation has not yet sufficiently proved, whether, under favourable circumstances, this, or any other kind of cyst of the ovary, is ever formed alone, unaccompanied by any other change of this organ. 3. Most frequently cancer is at the same time developed; masses of this nature existing either upon or between the layers of the cyst. Here I must observe, that the sarcomatous substances, so commonly attending ovarial cysts, are not usually regarded by British surgeons as truly carcinomatous; nor can I discover that Delpech brings any proof of the correctness of this part of his observations. The question is also a material one, inasmuch as it has great influence on the practical point, whether paracentesis and other active measures should be undertaken or not? 4. The statement, that there are always several cysts, does not agree with Dr. Baillie's account of the whole ovary being sometimes converted into a capsule. (*Works, by Wardrop*, vol. ii. p. 315.) In their structure they are alike, though their parietes may differ in thickness; but the nature of the matter which one cyst contains may be very different from what is included in another, independently of the effect of any incidental inflammation. This remark coincides with what Dr. Baillie has said on the same point. 5. Only one cyst attains a vast magnitude, so as to fill the cavity of the abdomen; and, though the others increase, they do not exceed a middling size. 6. The parietes of the cysts do not become thin in proportion to their distention; but, on the contrary, grow thicker. 7. The cysts communicate with one another only accidentally. This disposition is sometimes remarked after paracentesis, or some other surgical proceeding, calculated to produce an inflammation of some duration in the morbid mass; but Delpech thinks, that we have no ground for presuming that it ever happens spontaneously, and from the mere effect of distention or ulceration. 8. For the most part, the origin of the disease is quite clandestine; the swelling being the only thing at first taken notice of. If pains are sometimes experienced in the situation of the ovary, or in that of the uterus, it is not till the tumour has made considerable progress, and has been of long standing. Such pains are always exceedingly vague, and only manifested by some sympathetic ailment; and it may be doubted whether they may not rather depend upon distention, than organic disease. At all events, nothing justifies the suspicion of their dependance upon inflammation. 9. Inflammation sometimes originates spontaneously in an ovary containing cysts; but, more frequently, its cause is injudicious treatment. Hence arise particular symptoms, readily distinguished from such as belong to the organic disease. Dissections evince that the inflammation leads to a deposite of different quantities of concrete albuminous matter, or pus, in only some of the cysts. And Delpech believes that the inflammatory process does not readily establish itself, nor easily spread to the whole mass of an ovary in this state. 10. An ovarial cyst may enlarge in such a degree, that the whole abdomen is filled by it. When the surrounding peritoneum inflames, the cyst may become adherent to all the viscera, and to the parietes of the belly. Under these circumstances its strength is augmented by the support of all the circumjacent parts; and, if inflammation be kept off, and the accompanying indurated substances should not increase, the disease may remain stationary for many years. 11. The cyst may burst, and some of its contents pass into the peritoneum, where a dangerous inflammation may be the consequence. Several examples of this occurrence are recorded by Delpech. 12. The accident can

nardly be recognised with certainty by the symptoms; but it is to be apprehended when the tumour augments rapidly, attended with acute fixed pain. 13. Here the proper treatment will depend upon the consequences of the rupture. When absorption of the extravasated fluid ensues, the surgeon will be prudent not to interfere much; but, if this desirable event should not take place, Delpech recommends paracentesis to be performed on the opposite side. 14. As no treatment is known that will cure organic disease of the ovary, and active medicines create serious irritation in the abdominal viscera, which Delpech describes as peculiarly irritable in this disorder, he lays it down as a fundamental rule in practice, that they ought not to be employed. 15. As puncturing the tumour, when a fluctuation is evident, creates a risk of bringing on peritonitis, or such hemorrhage as cannot be commanded, the operation should never be done for the first time, unless the cyst be about to give way. Delpech advises the puncture to be generally made at the side of the hypogastrium, corresponding to the diseased ovary. If, however, the fluctuation should be plain at the bottom of the vagina, and the tumour should not quit this place, in the different attitudes of the patient, he considers that this is the most advantageous situation for the puncture. If the cyst should form a projection at the navel, as sometimes happens, this part should be selected. 16. A puncture may be undertaken with more confidence, when one has been previously made *without ill consequences*, provided care be taken to make the opening precisely in the situation of the former. 17. In these last cases, if the patient's strength be not too much reduced, Delpech sanctions the attempt to establish an artificial fistula, by leaving a gum catheter in the puncture; but if inflammation come on, the scheme is to be renounced. 18. Le Dran's operation of making a free incision into the cyst (see *Paracentesis*) is condemned, as likely to excite peritonitis. This consequence, he thinks, the more likely to follow, as experience proves, that such treatment produces extensive mortification of the cyst. 19. An inflammation of the large cavity of the cyst, he conceives, is sometimes the cause of death, even without peritonitis. 20. Everything that is known respecting ovarial cysts, proves to Delpech that they are incapable of undergoing the kind of diminution which takes place in the sero-mucous ones; that, when punctured and kept open, whether they inflame or not, they subside, and are thrown into folds, but still retain their cavity, and the property of secreting the same fluid as heretofore; that, when the puncture closes, the cyst fills and expands again, sometimes with an unusual degree of pain, in consequence of the adhesions formed in its empty state; that the punctured part then generally reopens spontaneously; that the inflammation, caused by opening the cyst with a bistoury, is not more effectual in bringing on adhesive inflammation, than what follows either a simple puncture, or this plan, succeeded by that of keeping up a fistulous aperture; that the practice of an incision, and its consequent perils, have most frequently only terminated in the formation of such an opening; that, in a few rare examples, in which the operation produced a complete obliteration of the cavity, the whole cyst was destroyed by gangrene. 21. The project of treating an ovarial cyst like a hydrocele, is strongly disapproved of by Delpech, with whose opinion the observation of some attempts of this kind leads me fully to coincide. (See *Paracentesis*.)

It appears to me, that notwithstanding the possibility of the accident, Delpech overrates the danger of internal homorrhage from puncturing an ovarial cyst; and that he ought to have admitted the severe indisposition, the oppression of breathing, the retention of urine, and other urgent symptoms, often produced by the great pressure of the swelling, as circumstances rendering the operation indispensable for the present relief of the patient. Sir Astley Cooper informs me, that he has not met with any fatal case from bleeding into the cyst. In one instance, to which I was called by Dr. Epps, I punctured an ovarial cyst through the linea alba, and the fluid discharged was considerably tinged with blood; but, as the body was not opened after death, it was unknown whence the bleeding had proceeded, or whether any accumulation of blood had taken place in the cyst; an occurrence, of which Delpech had such apprehension. The reader may usefully compare what has been here said with that part of the article *Paracentesis* which treats of ovarial dropsy.—C.]

[OVARIAN TUMOURS. In addition to the cases named in my note as contained in the body of this Dictionary, Dr. Alban Goldsmith of New York has operated successfully by extirpation, and the case is reported in the N. A. Med. and Surg. Jour. for 1824. Since that time Dr. Goldsmith has repeated this operation in two cases, one of which was completely successful, but the other failed, solely, as he thinks, because he relied upon the animal ligature, which gave way some days after the operation, and the patient died, in consequence of secondary hemorrhage within the abdominal cavity.

Dr. Goldsmith relates a case in which he was concerned with the late Dr. M'Dowell of Kentucky, who was the first in this country to extirpate ovarian tumours, and who performed the operation oftener, and with greater success, than any other surgeon either in the old or new world. A woman who had long suffered from ascites, and had performed the operation of tapping upon herself no less than ninety times during a few years, having learned the use of the trocar and canula to perfection, applied to Dr. M'Dowell for a tumour which she supposed to be the cause of her dropsy, and besought him to cut it out. Dr. M'Dowell could feel a tumour of large size, occupying the site of a diseased ovary, and from its locality, proximity to the abdominal walls, and seemingly detached condition, decided upon the practicability of its removal. Both he and Dr. Goldsmith regarded the tumour as plainly ovarian, and thought the diagnosis so certain, that they were astonished, on opening the abdomen, to discover, that what they took to be a tumour was a mass of the intestines conglomerated by adhesions, so as to present through the abdominal walls the aspect of a tumour, and utterly deceive the touch. They abandoned the operation, which might be called an exploring one, and the woman died. This case goes to confirm the doctrine taught in the text by Mr. Cooper, that if there were no other reason against the attempt to extirpate ovarian tumours, the difficulty, not to say the impossibility, of making out a clear and safe diagnosis constitutes in itself a sufficient objection to the operation. I have known a number of these "exploring opera-

tions," as they are called, result disastrously like Dr. M'Dowell's case, for in several instances the operation has been abandoned, but the patient has died upon the table. To cut into the abdomen on an exploring expedition may well be regarded as of questionable morality, and is "most villanous surgery."

Professor Mussey, of Cincinnati, reports a case in which he performed a successful operation for ovarian disease by opening the sac, and effecting adhesion between its walls. His paper abounds with accurate and just criticism on the question of attempting the removal of these tumours. See Amer. Jour. for 1838.—REESE.]

[OXYMURIATIC ACID. Besides the nitrous and nitric acids, other medicines containing a large proportion of oxygen, and easy of decomposition, have been recommended as remedies for the venereal disease; viz., oxygenated vinegar, oxalic acid, oxygenated muriate of potash, &c. (See *Caldwell's Medical Theses*, vol. i. p. 111.) But, perhaps, nothing has been put to the test of experiment with greater expectation of success, than the oxygenated muriatic acid. Mr. Cruickshank made a very early trial of it in syphilitic cases, and, as is alleged, with the utmost benefit. He also employed the nitric acid, and the oxygenated muriate of potash, and found them eligible remedies. The latter medicine was likewise given by M. Alyon in cases of chancre and secondary ulcers, who found the good effects from it more expeditious and more certain than those of any mercurial preparation. (*Essai sur les Propriétés Médicinales de l'Oxygène, &c.* 8vo, Paris, an 7ième.) On the other hand, as much contrariety of sentiment, respecting the real and permanent efficacy of all these medicines, prevails in the numerous reports about them, as in the accounts delivered of the effects of the muriatic and nitric acid; and therefore I do not think that the reader, after the copious statements given in this book concerning the *nitric* and *nitrous acids*, (see *these words*,) would be pleased to hear again a repetition of very similar contradictions respecting the oxygenated muriatic acid. I may observe, however, that if oxygen be the principle on which the efficacy of many antisyphilitic remedies truly depends, this acid must possess greater virtue than the common muriatic acid. From ʒss. to ʒij. mixed in ʒviij. of water sweetened with sirup, may be taken in divided doses in the course of the day.

Oxygenated muriatic acid was strongly praised by Guyton de Morveau as a means of disinfecting sick-rooms, and purifying the air of crowded hospitals.—C.]

P

[PALATE, CONGENITAL FISSURE OF THE. This presents itself in three forms:—1. Where there is a simple slit in the middle of the vellum, without any loss of substance, or any fissure in the bony part of the palate. 2. With partial division of the bony palate, or roof of the mouth. 3. With complete division of the same part, in which case there is always a greater or lesser interspace between the two halves of it; and almost constantly likewise a fissure in the alveolary process and the lip. Hence, there are three kinds of operation, each of which is adapted to the particular variety of this congenital imperfection. 1. *Staphyloraphe*, applicable to examples, in which there is merely a narrow fissure, in the soft palate. *Staphyloplastic*, when there is a wide rent resembling a loss of substance; and *uranoplastic*, calculated for cases in which there is a real or a seeming loss of substance in the roof of the mouth.

1. *Staphyloraphe, process of M. Roux.*—The apparatus required consists, 1. Of three broad flattish ligatures, composed of three or four strong threads. 2. Of six small curved flat needles, two for each ligature. 3. A porte-aiguille. 4. A pair of dressing forceps. 5. A probe-pointed bistoury. 6. Scissors with long handles and short blades, bent laterally to an obtuse angle.

The patient being seated opposite the light, and the mouth kept open, the surgeon takes hold of the right edge of the fissure with the forceps held in his left hand, while, with the right, he conveys into the pharynx the porte-aiguille, armed with a needle, the point of which is of course turned forwards. The point of the needle is then carried back to the posterior surface of the velum, and passed through it from behind forwards, near the lower end of it, and about three or four lines from the margin of the slit. The point of the needle is to be passed out as far as practicable, and then taken hold of with the forceps. The porte-aiguille being now removed, the needle is drawn into the mouth with the forceps, and along with it the ligature, with which it is threaded. After the patient has recovered his tranquillity and washed out his mouth, the other end of the ligature is to be passed in a similar way through the left side of the velum, and the two ends are to be brought out of the mouth at the commissures of the lips. Then a second ligature is to be applied near the angle where the two sides of the velum meet, and a third at the middle point between the other two ligatures. The left side of the fissure is then seized, depressed, and rendered tense with the ring-handled forceps, and the excision of its margin begun with the curved scissors; and completed with a straight probe bistoury applied on the outer side of the forceps, and with its back directed towards the root of the tongue. Thus a slip is to be removed about half a line in breadth. Particular care must be taken to let the slip extend a little above the front angle of the fissure. The same proceedings are to be followed on the opposite side; the two incisions being made to join at an acute angle above the point just now specified. It only remains to tie the ligatures. The surgeon begins with the lowermost one, which is first to be tied in a simple knot. As soon as this has been duly tightened with the fore fingers, it is to be taken hold of with the ring-handled forceps, and kept from slipping, until another knot is made. The same plan is to be adopted with regard to the two upper ligatures. Finally, the two ends of each ligature are to be cut off with the scissors as useless.

No dressings are required, but the patient must refrain from talking, and as much as possible from swallowing even his spittle, which should be received in a vessel or on a handkerchief, in

proportion as it is secreted. Coughing, laughing, sneezing, &c., must likewise be avoided. Between the third and fourth days, one or both the upper ligatures may be taken away; but the lower one should be left a day or two longer. If the attempt at union fail above, which frequently happens, when the fissure extends into the roof of the mouth, the closure of it may yet be effected by the work of time, or it may be promoted by touching its edges with the nitrate of silver.

To the foregoing plan it is objected that, by passing the needles from behind forwards with their points out of sight, it is difficult to enter them with precision in the most desirable places. That when the ligatures have been introduced, the removal of the margins of the fissure, as executed by M. Roux, is exceedingly difficult. In fact, says M. Malgaigne, whatever pains be taken to stretch and draw downwards and inwards each half of the soft palate, it is always difficult, when the surgeon begins with the loose margin of the velum, to make a clean and regular incision through it; and if scissors are employed, there is a risk of cutting the threads. See *Man. de Méd. Opér.*, p. 473—477.

M. Berard's Method.—The surgeon seizes the left margin of the fissure with a pair of tenaculum forceps held in the left hand. With the right he holds the needle with the dressing forceps, the concavity of the needle being turned towards the free edge of the fissure. The needle is introduced from before backwards on a level with the upper angle of the slit, nearly three lines to the outer side of its free edge, and it is pushed on till the whole of its curved portion has traversed the velum. Its curve permits its point to be directed backwards and inwards, and to become visible in the fissure. The operator now relinquishes the free edge of the velum, and with the same forceps, which serve to keep it tense, he takes hold of the part of the needle projecting backwards. A slight traction backwards and towards the side opposite that of the entrance of the needle, serves to disengage its heel; and the needle is then brought from behind forwards through the fissure, and next out of the mouth, together with the ligature connected with it. Another ligature is now passed in a similar manner through the right lip of the fissure. The second needle draws a ligature after it in the form of a noose, which is detached from the needle, and the deep end of the ligature passed through it. A second or a third noose is made in the same way according to the extent of the fissure, care being taken to enter each needle about three lines from the free margin of the division. The nooses being now drawn down to keep the ligatures out of the way of the knife, the left side of the fissure is once more taken hold of with the forceps, and its edges removed with a bistoury, which is passed through the soft palate one line above the angle of the fissure, with its back towards the roof of the mouth, and its edge downwards. The same proceeding is adopted on the other side, and the ligatures tied.

Mr. N. R. Smith's Method.—This gentleman, a surgeon in the United States, employs a very simple needle, mounted on a handle, and with a curve, the radius of which is about half an inch. At two or three lines from its point is a slit open at its posterior end, extending along one side of the needle to its middle. In front of this eye or slit the needle is broader than behind, which facilitates the passage of the part of the instrument which follows. The eye having had the ligature introduced through it, the curved portion of the needle is conveyed into the mouth beyond the palatine fissure, and its point carried behind the middle of the uvula, and passed through the latter part from behind forwards. As soon as the point of the needle has passed sufficiently forwards, and the ligature in the slit of the instrument is perceived, the thread is to be taken hold of with a tenaculum, and having been disengaged from the eye, or slit in the needle, the latter instrument is withdrawn. A second ligature is to be passed half an inch higher up; and in some cases a third, at an equal distance from the second. With the ends of the ligature passed through the uvula, this part is now drawn forwards, and the fissure in the soft palate having been then brought nearly into a horizontal position, its edges are to be cut off with scissors, either straight or curved laterally, or with the aid of a knife and a pair of forceps. After the ligatures have been tied, they are to be cut off near the knots.

Mr. Liston's Method.—A narrow sharp-pointed knife, held by the further end of the handle, is introduced through the edge of the fissure at its anterior margin, "and run back to the apex of the one half of the uvula. This may be laid hold of, and made tense by means of the sharp-pointed forceps. The same proceeding is repeated on the other side." The ligatures are introduced with needles, fixed in handles, and of different sizes and curvatures, the eyes being near their points. They are passed through the velum about a quarter of an inch from its free edge and towards it, and through two-thirds of its thickness. Each needle carries a double ligature, the noose of which is caught by a blunt hook, and pulled out into the mouth, whilst the instrument is withdrawn. A second and smaller ligature is carried through opposite to the first, and by means of this second thread, the first and double one is brought through. By a repetition of this plan, two, three, or more points of interrupted suture are made. After the edges have been put together by one or two points, no difficulty will be experienced in carrying others through both edges by means of a more curved instrument in a handle, or by the use of a small needle carried in the points of a pair of strong and well-fitted forceps. Before the ligatures are finally secured, the parts being put upon the stretch, an incision should be made on each side towards the alveolar ridge through the anterior surface of the velum. By this method, Mr. Liston finds that the edges may be more easily brought together, and the strain is taken off the threads, so that there is less risk of their making their way out by ulceration. Mr. Liston deems the operation very liable to failure. (*On Practical Surgery*, p. 472.)

Staphyloplastic.—One modification of it consists in facilitating the approximation of the edges of the fissure to one another, by an incision made along the palate, on each side of the division. The ligatures, arranged in the usual way, will now draw the margins of the fissures together, when, without such incisions, this object would be impracticable. This method is followed by Dieffenbach.

The *Indian staphyloplastic* consists in raising up a flap of soft parts from the roof of the mouth, and twisting its pedicle round, so that

the flap may be adapted, by means of suture, to the loss of substance in the palate. I do not deem it necessary to enter further into the various plans of repairing deficiencies and apertures in the palate, on Tagliacotian principles. The mode of proceeding in different cases must be decided by the particular nature of them.

[PATELLA. Dr. Mutter, of Philadelphia, has performed Dieffenbach's operation for displaced patella with perfect success, and in another case he has replaced the patella by a new method. As this gentleman is about publishing a new work on Surgery, he will furnish the details of these and other operations, for which my limits are inadequate.—REESE.]

[PERIOSTITIS. Inflammation of the periosteum. Is sometimes an idiopathic affection excited by cold, or mechanical injuries; sometimes a secondary complaint, produced by various deranged states of the general health, as by rheumatism, syphilis, and the abuse of mercury. In the idiopathic form, the treatment should be antiphlogistic, comprising bleeding, leeches, calomel, saline, aperient, and diaphoretic medicines, and poultices and fomentations. In the chronic stage, blistering, and light tonic alterative medicines, are indicated. If no relief be experienced from these, mercury, or incision down to the bone, has been found to answer. The treatment of periostitis occurring as a symptom of some constitutional disease, differ according to the nature of the original complaint; calomel and opium, hydriodate of potash, with sarsaparilla and colchicum, are remedies, whose usefulness in such cases is universally known. —C.]

[PESSARY. M. J. Cloquet gives the particulars of a case, in which a pessary was met with in the body of an old woman, the broad lower end of which had perforated the rectum, while the upper narrower one had produced ulceration of the vesico-vaginal septum, and entered the bladder. Three-fourths of the interior of its wider part were filled with a white crystallized concretion, strongly adherent to it, with brownish stercoraceous matter between the large crystallizations. The upper narrower end was incrusted with a concretion, of irregular shape but smooth surface, and yellowish colour, composed of uric acid. (See *Jules Cloquet*, in *Pathol. Chir.*, p. 100. 4to, Paris, 1831.)—C.]

[This case will probably be hailed by those American surgeons who vehemently oppose the use of pessaries, as an argumentum ad hominem on their side of the question. But such extreme cases prove nothing on either side, except that these instruments, like all others, may be misapplied. In the Southern Medical Journal there is an article by Professor P. F. Eve, protesting against the use of pessaries under any circumstances, and citing numerous medical authorities against them as useless and mischievous. While in the Philadelphia practice of Midwifery by Dr. Meigs, the reader may see an elaborate argument in their favor, not as a universal remedy for prolapsus uteri, but as a valuable auxiliary in certain cases. Dr. Meigs gives the preference to the globular form, and to the metallic material for these instruments. The primitive and most ancient form was that of the globe, for Hippocrates recommended the pomegranate previously soaked in wine, as a pessary. Dr. Physick, while a pupil of John Hunter, employed a billiard ball of ivory, and the only objection was its weight. He ever afterwards employed the globular form, but preferred a hollow globe of silver covered with gold. Almost every variety of form and material has been used by different surgeons, and to vary the size and shape of pessaries in different cases is found indispensable.

Dr. Saml. K. Jennings, of Baltimore, after extensive experience in the treatment of prolapsus and other forms of uterine disease, has recently proposed a new form of pessary, which he thinks is adapted to rectify all the evils ascribed to those instruments, and better fitted to fulfil all the requisite indications. His own description of the instrument is here inserted, so far as is necessary to explain its principles.

"If we duly consider the anatomy of the organ to be supported by a pessary, we cannot fail to perceive, that the instrument, if it shall have good pretension to a philosophical adaptation, ought to fill the cavity of the vagina without inconvenient distention, either lateral or longitudinal. It should reach about four inches above the os externum, and should have a neck, by which the entire weight of the organ and instrument may be made to rest upon a bandage or cushion fitted for that purpose. Its upper extremity should occupy the cul-de-sac, lifting it above the neck, and present a suitable cavity on its anterior side, into which it shall receive the neck of the womb. This last named adjustment will secure to the uterus the necessary elevation, and to the fundus of the organ an inclination in conformity to its natural angle with the vagina; and the neck, when received into the cavity provided for that purpose, will subserve to keep the instrument in its proper position. On the anterior side of the instrument there should be a sulcus or groove of sufficient capacity to protect the urethra. This groove will also enable the patient at any time, very conveniently, with the end of the forefinger, to ascertain whether the instrument retains its intended position; and it will make a channel for the exit of the secretions.

"A pessary made to correspond to these views, should have its body about three and a half to four inches long. Its shape should be ovato-oblong. Its ovate part should measure about two inches in length, and from an inch to an inch and a half, or an inch and three-fourths, in some instances two inches and a fourth in breadth. Its lengthened or smaller end should measure about an inch and a half or an inch and three-fourths in length, and three-fourths of an inch to an inch and a quarter, or an inch and a half in breadth. To the small end there should be attached a neck or stem, about an inch and a half in length, having at its lower extremity two circular buttons, seven-eighths of an inch in diameter, and one-fourth of an inch apart, for the purpose of receiving and holding the bandage which is intended to sustain its weight. At the upper or larger end of the ovated part, and on its anterior side, there should be an ovated cavity, as large as the size of the instrument will admit. The rotundity of the ovated end, aided by this cavity, will sufficiently fill the cul-de-sac, and compel the neck to resume and retain its natural position and angle; and the neck thus supported by the cavity will in turn prevent any change in the position of the instrument. Its lower or lengthened end should be sulcated on its anterior side for the protection of the urethra, and there should be a circular indent in the upper anterior side of the ovated cavity, to make room for the neck."

Dr. Jennings has published a brief treatise on the subject, which explains his peculiar views. In old cases of prolapsus, complicated with more or less retroversion of the uterus, he alleges that this latter displacement is attended with a subacute inflammatory condition of the parts, resulting in adhesions, sometimes extensive and obstinate, corresponding to the extent and time of pre-existing irritation. These adhesions resemble tumours on examination per rectum, by the rigidity of the contractions, and he insists that all attempts to maintain the uterus in situ, even after it is replaced, will be unavailing until these abnormal adhesions and contractions are broken up. The manipulation he recommends for this purpose is performed with the finger in the rectum, making lateral pressure to the necessary extent, and repeating the process at suitable intervals, until the uterus can be elevated to its normal state without pain or inconvenience. Meanwhile he advises general and local depletion, corresponding to the pathological state found to be present.

In the Amer. Jour. for 1842, Dr. J. P. Mettaure, of Virginia, reports a highly interesting case of Menorrhagia, connected with malposition of the uterus, with adhesion of its cervix and os tincæ to corresponding portions of the vagina. —REESE.]

[PHLEGMASIA DOLENS. A swelling of the lower extremities, the consequence of crural phlebitis. It is mostly seen in puerperal women, but sometimes in other women, who have not been pregnant; and now and then in the male sex. I have had two male patients of this kind; one of them was a soldier, in a military hospital at Cambray, during the war; the other was a man who died in the Queen's Bench Infirmary. In the *post mortem* examination, the external iliac and other veins were found completely obstructed. Dr. Davis, of University College, was the first who proved by dissection, that phlegmasia dolens depended on inflammation of the iliac and femoral veins. (See *Med. Chir. Trans.*, vol. xii. 1823.) One of his cases occurred in 1817, considerably prior to the examples recorded by M. Bouillaud in 1823. The latter states, however, that Chaussier and Meckel had related still earlier instances of phlegmasia dolens in puerperal women, where the crural veins had been found inflamed and obstructed. (See *Archiv. de Méd.*, t. ii. Janv. 1823.)—C.]

[PHYMOSIS. Dr. Eve, of Georgia, has several times performed the operation for Phymosis on the plan proposed by M. Cloquet, making small incisions on each side of the frenum, after having retracted the skin as far as possible.—REESE.]

[PNEUMOTHORAX; (from πνευμα, and θωραξ.) An accumulation of air in the sac of the pleura. Air may pass into this situation either from the lung or bronchial tubes, or through the parietes of the chest. An example of the former is afforded by the rupture of the pleura pulmonalis, by the bursting of a tubercular cavity communicating with the bronchial tubes; and an instance of the latter is afforded by the pneumothorax consequent to certain penetrating wounds of the chest. Air is also stated by M. Itard to be sometimes generated within the sac of the pleura. This last occurrence is rare: and Dr. Houghton considers that the doctrine of pneumothorax being ever formed by the decomposition of a pleuritic effusion, is by no means satisfactorily proved. (See *Cyclop. of Pract. Med.*, art. *Pneumothorax*.) According to Laennec, the pleura, in some very uncommon instances, secretes air: and the air so produced is occasionally accompanied by an effusion of serous or purulent fluid. "This variety (Dr. Houghton remarks) has not been decidedly established by the observation of other pathologists, and we record its existence merely on his authority, and on that of Andral, who relates a case of it, (*Clin. Med.*, t. ii. p. 512,) in which, however, this origin was not unquestionably proved." (*Op.* cit.)

In cases of pneumothorax produced by the bursting of a tubercular abscess into the pleura, the existence of a large cavity, or even of numerous tubercles, is by no means essential. Dr. Houghton has known pneumothorax occur, where the cavity which led to the perforation was smaller than a nut. Andral and others met with cases, where only five or six tubercles existed in the lung; and Dr. Townsend had one remarkable case, where it followed the bursting of a single tubercle which had been formed immediately under the pleura, all the rest of the lung being perfectly free from tubercles. The passage of the contents of the tubercle, and of the air, into the sac of the pleura, which mostly happens on the left side, always brings on a severe attack of acute pleuritis. If this be not speedily mortal, the effused lymph soon becomes organized, and forms a factitious membrane, overlaying the whole surface of the compressed lung, as a deposition upon the pleura, which lies under it, of its natural thickness. The lung itself lies compressed and flattened against the spinal column and mediastinum; and in cases which have lasted some time, it generally becomes reduced to about one-fourth of its natural dimensions; and then, if cut into, its substance is found to be so condensed as to present the appearance of what is termed carnified lung. The perforation, by which the air escapes from the lung into the sac of the pleura during inspiration, becomes fistulous; and as for the air itself, if it be discharged by puncturing the thorax, it is found to be generally an inodorous gas, little different from the atmospheric air, whence it was originally derived. (See *Dr. John Davy*, in *Phil. Trans.* 1824; and *Dr. Apjohn*, in *Trans of Assoc. of College of Physicians, Dublin*, vol. v.)

In the majority of cases, the air, although it has a free passage into the sac of the pleura, cannot return into the lung during expiration, owing to the valvular disposition of the fistula; and if this impediment did not exist, still the air could not return into the lung, because the air-cells are full of air. The fistula is closed, exactly in the same manner as the valve of the bellows prevents the air from going out by the aperture through which it entered. The consequence is, that the air exerts a pressure within the sac, and that such pressure continues to increase so long as the communication remains open. The space occupied by the air is much greater than that occupied by pus, or other fluid: and it seems evident to Dr. Houghton, that the chief part of the pressure must be produced by the air, and not by the other fluid.

This species of pneumothorax is almost invariably preceded by the usual symptoms of phthisis, cough, hæmoptysis, emaciation, night sweats, &c. Then, at the moment when the air first insinuates itself into the sac of the pleura, the patient is sometimes conscious of the occurrence, or has a sensation of something

having suddenly given way in the chest. Empyema, as Dr. Houghton observes, being constantly an accompaniment of this variety of pneumothorax, the symptoms of the latter are necessarily joined with those of the former. Hence the insufficiency of the rational symptoms for the diagnosis. "We find the symptoms of empyema set down as dyspnœa and pain, (cough and expectoration,) decubitus on one side, dilatation of the side, displacement of the heart, depression of the diaphragm, and hectic fever." (See *Empyema.*) The same catalogue precisely makes up the rational symptoms in pneumothorax.

The dyspnœa and pain which immediately follow the bursting of the tubercle, and the first entrance of air into the sac of the pleura, are nearly simultaneous with the sensation above described; but they are still more constantly present, and therefore (as Dr. Houghton observes) of more value in the diagnosis. Yet pneumothorax has been known to take place without either violent pain, or sudden dyspnœa. (*Townsend*, in *Trans. of Dublin College*, vol. v.; and *Houghton*, in *Dublin Journ. of Med. Science*, No. 3.)

The dyspnœa, which usually continues during the whole course of pneumothorax, is more urgent and distressing than that attending chronic empyema. This is accounted for by the great elasticity and condensation of the air, so that even the greatest expansion of the thorax in inspiration can but very partially overcome its reaction, and therefore dyspnœa, resulting from the compression, is thus but trivially mitigated. (See *Cyclop. of Pract. Med.*, art. *Pneumothorax.*)

Different writers give different accounts of the side on which a patient with pneumothorax prefers to lie. "In empyema (Dr. Duncan observes) the patients commonly lie on the affected side; and in pneumothorax, on the sound one." (*Ed. Med. Journ.*, No. 28, p. 327.) In relation to this point, Dr. Houghton admits the fact, that, in empyema, the dyspnœa is caused by the pressure of fluid alone, and that it is chiefly for the purpose of relieving the mediastinum, and opposite lung, of its weight and pressure, that decubitus takes place on the affected side. (See *Empyema.*) But, he observes, in pneumothorax, the compression of the internal organs is as complete, if not more so, although caused by air; and, if the weight of even an inconsiderable quantity of fluid should be added to them, already suffering under this great compression, the patient will instinctively obviate this by lying on the affected side. According to Dr. Houghton's experience, this position, *cæteris paribus*, is always preferred.

The side where pneumothorax exists, is but slightly or not at all elevated during inspiration; and, on being measured, generally is found to be larger than the opposite one. But in other disorders and in empyema, the intercostal spaces are widened and occasionally protrude beyond the level of the ribs. But the œdema of the integuments of the side, sometimes noticed in empyema, is not observed in pneumothorax, although M. Louis and others have remarked an œdematous state of the corresponding arm.

According to Dr. Houghton, less compression seems requisite to produce displacement of the heart and depression of the diaphragm than dilatation of the side; for the latter has been absent where the heart has been thrust considerably out of its place, and a sensible fulness produced in the corresponding hypochondrium by the depression of the diaphragm.

In addition to the foregoing *rational* symptoms of pneumothorax, is the febrile disturbance, which always speedily follows the escape of air by perforation of the tubercular cavity, and is in fact the fever of pleuritis. If the immediate consequences of it are not fatal, this fever subsides into the hectic of phthisis, which existed previously to the bursting of the tubercle.

The *physical* symptoms of pneumothorax are highly deserving of attention. Whenever air and fluid exist together in the sac of the pleura, if the trunk be shaken abruptly, the splash of the liquid against the walls of the thorax is often distinctly heard by the patient, or by any one who places his ear on or near the chest. This sound can only be produced where air and fluid are both present: if either is absent, no splashing sound is heard. The action of suddenly shaking the trunk to acquire this information, is termed *succussion.*

One of the positive signs of pneumothorax is a metallic tinkling, or ringing sound, discerned with the naked ear, and still better with the stethoscope. It is compared to the sound occasioned by the dropping of a pin into a large wine-glass, or touching gently a sonorous porcelain vase with a quill. It is audible during coughing, speaking, and sometimes during respiration.

The general result of pneumothorax from perforation of the lung by tubercle, is death. Laennec is well known to have believed in the possibility of the cicatrization of tubercular cavities; and hence it has been conceived, that, in this case, a recovery is not absolutely prohibited. The chances of it, however, appear exceedingly poor. Even Laennec himself admits, that the effusion of air cannot exist for any length of time, without giving rise to very severe symptoms, and even death. M. Louis only speaks of the result, with the view of calculating the time which elapses between the period of perforation and death. (*Récherches sur la Phthisie*, p. 487.) Dr. Stokes relates a case, which lasted five months, as the longest at that time on record. (*Trans. of King's and Queen's College*, vol. v.; and *Houghton, in Cyclop. of Pract. Med.*)

These circumstances are very discouraging to the performance of any operation for the discharge of the air. Cases will occur, where venesection, leeches, anodynes, &c., will fail to prevent the dyspnœa from increasing to such a pitch as to threaten the patient with suffocation. Then the only means of enabling the patient to live longer, is making a small puncture in the chest. This is mostly followed by great relief; which, however, is only temporary. The failure of the operation is ascribed by Dr. Houghton to the readiness which, in such cases, the false membrane and pleura have to inflame and become gangrenous.

Pneumothorax, from the bursting of an abscess of the lung, is rare; and when it happens, the empyema is generally circumscribed. Dr. Houghton suspects, that this must have been the case in the examples of recovery recorded by Dr. Archer, (*Trans. of King's and Queen's College,*) and Dr. Hawthorne, (*Edinb. Med. Journ.*, No. 61.)—C.]

[POLYPUS. Professor Gilman, of New York, has published in the New York Med. Gaz. for 1841, a report of a case of polypus uteri, which he removed by excision, and which he accom-

panies by the grounds of his preference of the knife to the ligature in this disease. An abstract of this valuable paper may be found in the Amer. Journ. for 1841.

Dr. John Watson, of New York, has published in the Amer. Journ. for 1842, an elaborate paper on the pathology and treatment of polypous tumours of the nasal fossæ, with other observations on tumours, in which the whole subject is illustrated by reports of interesting cases, and which will be found to possess great practical value.

The following case of nasal operation for polypus will be found to possess the merit of originality, and is very creditable to the surgeon, Dr. Mott, of New York:—

The case was a large fibrous tumour from the nasal cavity of the left side. The operation consisted in making an incision through the soft parts, commencing a little on the mesial side of the internal angular process of the os frontis, and extending downwards to the upper lip, which was divided about three lines from the angle of the mouth. Two flaps were then reflected, the internal including the cartilaginous parts of the nose, and the tissues covering the os nasi of the left side; the external laying bare the bone as far as the infra-orbital foramen. The anterior part of the tumour was now somewhat more distinctly seen, and the nasal cavity was farther exposed by sawing, vertically, through the os nasi as far as the transverse suture, so as to avoid the descending plate of the ethmoid. The superior maxillary bone was now divided in a line from the upper part of this cut to a point opposite the second bicuspid tooth, and on a level with the floor of the nostrils. Another section was made from the termination of the last, extending horizontally inwards towards the vomer. The osseous parts comprising the os nasi, a considerable portion of the superior maxillary bone, and the os spongiosum inferius were then detached. The connexions of the tumour were partially separated, but the disease was so extensive, that a part had to be removed through the anterior opening, before the posterior attachments could be liberated. These having been detached, the larger portion of this extensive disease, which passed into the pharynx and completely plugged up the posterior nares, was removed by introducing through the mouth a large curved vulsellum and forceps, and seizing the mass as it descended into the pharynx. (See *Amer. Journ. of Med. Science*, for January, 1842.)

Dr. John Watson, of New York, has published in the Amer. Journal for April, 1842, an essay on polypous tumours of the nasal fossæ, to which I can only refer the reader. It abounds in valuable practical information on this topic.

Dr. Joseph Parish, of Philadelphia, was successful in removing polypi from the posterior nares, which he effected by ligature in formidable cases, at the Pennsylvania Hospital.

Professor Eve, of Georgia, reports an operation in the South. Med. and Surg. Journ. for 1836, in which he removed a large fibrous polypus from the base of the cranium, after repeated unsuccessful attempts to remove it. The tumour filled the anterior and posterior nares, distended the antrum, protruded the eye, depressed the molar teeth, and frightfully deformed the cheek of the right side, and it had projected into the left antrum, while it distended the throat posteriorly, and pressed upon the palate, which had been partly removed by a previous operation. It was found intimately adhering to the basilar processes of the occipital and sphenoid bones, and to the internal plate of the pterygoid process. This intrepid proceeding was completed by the entire removal of the tumour, and the patient recovered with very little deformity of the face, and suffering only from the fissure in the palate which became necessary in the operation, and which failed to unite, though the interrupted suture was employed for the purpose. The operation of staphyloraphy is contemplated, as the patient has recovered his health, is an industrious farmer, and since married.

Dr. E. H. Dixon has contrived an instrument for the removal of polypi of the uterus by ligature, which, from its simplicity and adaptation to the purpose, possesses great merit. A paper on the subject, with a report of cases in which it has been successfully used, may be found in the 18th No. of the 25th vol. of the Boston Med. and Surg. Journal.—REESE.]

[PORRIGO. The late Dr. Joseph Parish, of Philadelphia, was remarkably successful in the treatment of Porrigo or Tinea capitis, and his son, Dr. Isaac Parish, has politely furnished me with his mode of treatment. He shaved the scalp as closely as possible, and then applied an emollient poultice for several days in succession, frequently renewing it. He then dressed the whole eruption with tar ointment, washing frequently with Castile soap and water. If the cure was slow, he again returned to the poulticing, and afterwards repeated the dressing. His success, both in hospital and private practice, was proverbial, so that he was consulted far and near for this class of diseases. Hence the simplicity of his remedies is worthy of imitation, especially in view of the obstinacy and difficulty of cure in these affections, proverbial among practitioners.—REESE.]

[PTYALISM. Dr. Fahnestock has published a paper in the *Amer. Jour. of Med. and Phys. Sciences*, vol. v., on the efficacy of the *rhus glabrum* as a remedy for ptyalism. He observes, that the medications in use intended to check inordinate and protracted salivations are all of a highly stimulating, astringent, and often corrosive nature, such as borax, myrrh, alum, nitric acid, &c., which seldom fail to aggravate the sufferings, and create deeper-seated irritations. Having seen very alarming and even fatal effects from salivation, and the remedies employed to control it, his attention was directed to the use of the gentle astringents, such as common tea, &c.; and finding much advantage from these, the experiments were extended to articles still milder, as the elm, sassafras, and *sumach*; from the latter of which he has derived peculiar benefit, and continues to use it with uniform and unparalleled success. An infusion of the inner bark of the root of the rhus glabrum is a very mild, mucilaginous refrigerant; moderately astringent, cooling and soothing to the irritated surface of the mouth and throat, and can be applied at any stage, and even to children. It acts by allaying and obstructing excitement, sheathing the delicate surfaces, and healing abrasions.

It is highly important, however, to distinguish the several species of rhus, and particularly the vernix, which resembles the glabrum very closely, but is very poisonous.—(See *Barton's Essay towards a Materia Medica of the United States.*—C.]

[In the Amer. Jour. of Med. Sciences for 1835,

Dr. Young, of Chester, published an account of an epidemic ptyalism which he witnessed, similar to that previously described by Dr. Coates of Philadelphia, in the N. A. Med. and Surg. Jour. Dr. Joseph Parish, of Philadelphia, was the first to direct the attention of the profession to this subject. It occurs most frequently among the poor, and was ascribed by him to confined air, impoverished diet, &c. The symptoms are thus described by him. A severe sore mouth, closely resembling mercurial ptyalism, even in the fetid breath. The cheeks become thickened and glossy, a sloughing ulceration soon follows inside the mouth, excessive discharge of saliva, extensive sphacelation, and occasionally fatal. In many cases no mercury or other medicine had been taken. Dr. Parish succeeded in curing numerous cases by the liberal use of bark, generous diet, and a solution of the sulphate of zinc with honey, as a local application.—REESE.]

R.

[RHINOPLASTIC. In 1837, Dr. John Mason Warren, of Boston, performed the first successful case of the Rhinoplastic operation ever published in America. It had been previously attempted, but failed to satisfy either the patient or the surgeon. In 1840, the same surgeon repeated this operation four times, the first on a female by the Indian method, the flap being taken from the forehead, and he effected in this case the restoration of the entire nose. In the second case he employed the Italian or Taliacotian method, the flap being transplanted from the forearm, and this is the first successful case by this method in America. In the third case he restored the alæ of the nose by sliding the flap from the cheek, on the plan denominated by the French surgeons, "autoplastie par glessment du lambeau."

In the fourth instance he again adopted the Italian method for the restoration of the tip and alæ of the nose, the flap being taken from over the biceps muscle. At the end of 72 hours, adhesion was sufficient to allow of the separation of the flap, which is the shortest time on record in which the separation has been successfully accomplished. The only surgeons in Europe who have attempted this operation since the times of Taliacotius, are Delpech of Montpellier, and Graeffe of Berlin. It was not until the fourteenth day that Graeffe, in his first case, separated the nose from the arm, and it was a year before the case was successful. In his second case, the flap was separated at the end of six days. (See Labat de Rhinoplastie.) In this last case of Dr. Warren, the patient was well in two months, and scarcely a trace of the operation is visible. This case has not been before published, but the others are reported at length in the Boston Med. and Surg. Jour., to which I must refer the reader. Sufficient time has now elapsed to judge of the permanency of the success which has crowned these surgical achievements.

At first it has been observed in Dr. Warren's cases, that the sensations in the new nose were referred by the patient to the place from which the skin was borrowed, to the forehead in those cured by the Indian method, and to the arm in the Taliacotian examples, but this morbid state of the sensations is not permanent. The pins were used in his first case but the interrupted suture was afterwards preferred, and is found to be fully adequate of retaining the parts in adaptation, and to present less hinderance to the desired adhesion. Dr. Warren has thus proved that this operation is safe, and may succeed; but he has constructed a new nose, which is so natural in appearance that no trace of the operation can be discovered, unless the attention is particularly called to the fact. He has thus restored to society and to usefulness both male and female patients, who were exiles by reason of their hideous deformity of countenance. See *Autoplastic.*

Dr. Geo. M'Clellan, of Philadelphia, has performed the Rhinoplastic operation four times with complete success. He adopted the Indian method. Dr. Gibson of the same city has also repeated this operation eight times successfully since 1827, the date of his first attempt at Rhinoplasty. He has repeatedly performed Urethroplasty and Blepharoplasty. Dr. Mutter, also of Philadelphia, has reported a case of Rhinoplasty, to which Velpeau awards the merit of originality in his late work on operative surgery. See Amer. Jour. Med. Sci., No. 43, for 1838. The same surgeon has since repeated this operation in five cases.

Dr. Mussey, of Cincinnati, has performed the Rhinoplastic operation in two cases; one by the Indian method, successful, the other by the Italian mode, failed, in consequence of the restlessness of the patient.—REESE.]

[RIBS. Dr. J. C. Warren, of Boston, has twice excised portions of the ribs in cases of osteosarcoma, and in both cases successfully. Dr. Valentine Mott, of New York, has also performed this operation in a similar case with complete success, and Dr. M'Clellan, of Philadelphia, has removed portions of the ribs four times. In one of these cases, Dr. M'Clellan removed a tumour, the result of spina ventosa, involving portions of several of the ribs, and projecting into the right side, displacing the diaphragm and pleura, and by its pressure very seriously impeding respiration. This formidable operation was completely successful, the tumour weighing eleven pounds.—REESE.]

S.

[SILVER, NITRATE OF. (*Lunar Caustic.*) One of the best of the milder caustics. Its utility in stimulating indolent ulcers, and keeping granulations from rising too much, is well known to every surgeon. Mr. Hunter sanctions its application in the early stage of a chancre, while absorption of the syphilitic virus may not yet have taken place. He directs the caustic to

be scraped to a point, like a black-lead pencil; every part of the chancre to be touched with it, and the repetition of this process till the last slough thrown off leaves the sore florid and healthy. The plan has been advocated by many other surgeons, in the hope that it may lessen the chance of the constitution becoming affected; and it is occasionally resorted to by those who use mercury, as well as by others who trust to other means for the cure of the venereal disease.

The important use of the nitrate of silver in the cure of numerous diseases which fall under the care of surgeons, I have noticed in various articles of this work. The late professor Delpech believed that it had greater power than any other escharotic or stimulant in expediting the process of cicatrization. I entertain the same belief. Its efficacy in the relief and cure of many diseases of the eye, may be learned from the explanations given in the articles Cornea, Iris, Ophthalmia, &c. As an application to this organ, it is used either in substance, or in the form of a lotion, or of the black ointment, containing from ten to twenty grains of the nitrate to each drachm of lard. Some examples of lupus, or noli me tangere, are benefited by the nitrate of silver, and a strong solution of it agrees well with certain obstinate ulcerations, which occur round the roots of the nails of the fingers and toes. The lotion is sometimes applied by means of a camel-hair brush; sometimes by means of lint; sometimes with a syringe; and occasionally by dropping it on the part, as, for instance, the eye.

In an interesting "*Essay on the Use of Nitrate of Silver*, ed. 2, 8vo, London, 1829," Mr. Higginbottom notices its influence in subduing inflammatory action. That it "should subdue the inflammation of phlegmon, or of a line of inflamed absorbents, arrest the spreading of erysipelas, prevent and modify the formation of pus, (says he,) are facts, I believe, totally new." In some cases of external inflammation, he finds it sufficient merely to blacken the cuticle; in others, it is necessary to produce a degree of vesication. In some instances, the application has appeared to prevent suppuration; in others, a plainly fluctuating fluid has been absorbed.

Mr. Higginbottom throws out a suggestion, that the application may prove useful also in internal inflammation, by inducing prompt vesication over the inflamed part, or even without it. But, for a particular account of its use in phlegmonous inflammation, whitlow, erysipelas, inflammation of the absorbents, wounds, ulcers, burns, and cases of hard painful cicatrix from the latter injuries, I must refer to this gentleman's publication, in which will also be found observations on its employment, in examples of diseased joints, inflammation of the urethra, neuralgia, contracted rectum, ulceration of the tongue, eye, and navel of infants, and corns. In University College Hospital, I often employ it as a means of checking the extension of erysipelas, which sometimes will not pass beyond a black line made with it. Its use in strictures, and many of the cases here specified, is further explained in other parts of this Dictionary.—C.]

[Dr. Joseph Parish, of Philadelphia, introduced a new method of applying nitrate of silver to old ulcers. Instead of touching their edges with the caustic, he applied it to the centre of the ulcer, and found the effect more speedy and successful, the healthy action commencing in the centre and radiating rapidly to the circumference. In the Pennsylvania Alms House and Hospital this practice is now pursued.—Reese.]

[Spina Bifida. Dr. Sherwood, of Rutland, removed this disease by excision with complete success in 1811, and the next year Dr. A. H. Stevens, of New York, cured an aggravated case by a modification of Sir A. Cooper's method, by puncture.—Reese.]

[Stammering. This afflictive defect, of which there are many sufferers, is one which, whether dependant on physical causes, or, as it is more frequently, belonging to the *morale* of the individual, is one for which no adequate or universally applicable remedy has ever been discovered, notwithstanding the devotion shown to the subject by many scientific and philanthropic individuals. Nor, indeed, was it ever imagined that surgery could have any thing to do with the subject, unless in those very rare cases in which the defect is dependant upon a contraction or congenital shortening of the *frenum linguæ*. Professor Dieffenbach, of Berlin, has, however, within the last year devised and executed an operation designed to relieve this defect, which he is led to believe is wholly physical, and depending on a malformation of the tongue, which he is of opinion can be removed by surgery. The operation is truly a formidable one, consisting as it does of carrying an incision through the tongue, near its root, in one of three ways, viz., 1st. The transverse horizontal division of the base of the tongue. 2d. The subcutaneous transverse division of the tongue, leaving the mucous membrane undivided. 3d. The horizontal division, with excision of a wedge-shaped portion of the tongue. He has repeated these several modes until he has decided that the last is the only one at all adequate to the removal of the infirmity.

Of the formidable nature of this operation, and of its hazards, Dieffenbach seems to be fully aware, for he says, "It can never be performed by any one who has not the temperament of an operator; the hemorrhage must hold all others at a respectful distance. The extent and importance of the operation, the possible danger to life, or loss of the tongue, through a want of skill in the assistants, who may tear it, when so nearly separated, or from mortification or ulceration of its connecting isthmus—these are contingencies rationally to be feared and which must be carefully weighed beforehand."

Dr. Parish, in his late *Annual Report on Surgery*, before the College of Physicians of Philadelphia, when commenting on this passage, uses language which will find a ready response from every discreet and conscientious surgeon.

"And yet, with these 'rational fears' before him, Professor Dieffenbach hesitates not to recommend the operation, and surgeons of eminence in France and England are rash enough to act upon the suggestion, even at the risk of human life. And this, too, when the results of the operation are doubtful, and before sufficient time has elapsed to pronounce with certainty upon them. No account of the operation of Dieffenbach having been performed in this country has reached us, and we hope, for the honour of American surgery, that no respectable operator will attempt it."

The suggestion implied in this operation of Dieffenbach, and the reports of its success which have reached this country, have led to the hope

that, in those cases of stammering which are dependant upon physical malformation of the tongue, if there be such, some operation may yet be devised for their relief. No reputable surgeon in America would hazard his professional character by "cutting boldly down through the tongue to its root, and excising from its centre a wedge-shaped portion of that member," in the faint hope of relieving a defect in the speech, nor for any other purpose, except it were rendered imperative for a disease threatening the speedy destruction of life. The well-known vascularity of the tongue, its peculiarity of structure, by reason of which hemorrhages from this member are so intractable, often demanding, even in slight wounds, the actual cautery; together with the hazard of inflammation by reason of the proximity of such a wound to the laryngeal and other adjacent structures; all these and similar dangers should deter any surgeon from so reprehensible an operation as that of Dieffenbach. Nevertheless, physical obstructions to the motions of the tongue, when ascertained in any case to be the cause of stammering, might possibly be remedied by surgery, without putting the life of the patient to hazard. Indeed, I have known the division of the frenum linguæ, in adult years, remove a most painful impediment in the speech, which manifestly depended upon an abnormal state of that chord, which had not been attended to in childhood. I succeeded thus in a gentleman, who has since become a clergyman, and is a fluent speaker. But my inquiries on this subject fully satisfy me that such examples among stammerers are rare, and that in most cases this infirmity is either the result of habit, or of some peculiar mental state, and is very seldom the result of any mere physical cause. The success of numerous professors of the art of curing stammerers, and which has become, with some of them, a source of fame and emolument, goes to confirm this view of the impediment in such cases, for the most popular of these professors have been known to rely upon a species of moral training, together with modifying the habits of the patient with respect to the manner of giving utterance to vocal sounds, including attention to the peculiarities of respiration. Such physiological and metaphysical exposition of the causes of the defect having been intelligibly explained to the stammerer, a very few practical lessons in elocution have removed from his mind the fallacious idea of its being a physical difficulty, and therefore incurable. And so soon as the stammerer acquired confidence in the ability of his teacher to cure the defect, it has been found that improvement immediately becomes manifest, proving that it is the mental state upon which the difficulty mainly depends.

Some surgeons, who have been consulted by stammerers, who have been desirous to submit to the operation, have devised and performed other and minor incisions in the tongue, and in a few instances the results have been temporarily favourable. These operations are for the most part free from danger, and have been repeated in this country by numerous surgeons. Professors Mott and Pattison, at the clinique of New York University, and Professor Parker, at that of the College of Physicians and Surgeons, have repeatedly divided the genio-hyo-glossi muscles, either by the knife or scissors, cutting closely to the symphisis of the lower jaw, when there is very little hemorrhage, and no troublesome consequences need be dreaded. The mouth being washed out with cold water, the hemorrhage ceases. In many of these cases the patients, who could neither read nor speak without a painful and ludicrous impediment, are so much benefited, that the instant after the incision they will read or speak with a fluency scarcely credible, and they will leave the operating room chattering away with freedom, which inspires a confident hope of entire relief. A single hour, however, too often dissipates the delusion, and they find themselves as bad as ever.

In these cases it is obvious that it is the *robuste foi*, as the French Mesmerizers are wont to say, and not the operation, which benefits the patient. Dr. Mott became so convinced of this that he contented himself with simply scarifying the mucous membrane of the tongue, and he found the same temporary improvement as in the cases when he divided the muscles of the tongue. Subsequently he performed acupuncturation, as originally proposed and practised by Dr. Wm. Detmold, of this city, by passing two or more needles entirely through the tongue, and withdrawing them after a few minutes, and the improvement in the speech of the patients was manifest and instantaneous; but, like the rest, the impediment returned, and similar results followed the repetition of acupuncturation a second and third time, which was often desired by the patients. Many of these cases I have seen, and these several operations may either of them possibly succeed, if the patients could be prepared to confide in them with absolute certainty, and their confidence remain unshaken afterward. This may be the secret of Dieffenbach's success, for to induce a patient to submit to his terrible incision, and incur its attendant dangers, very positive assurances of cure must be given; and if a patient should perchance escape the alarming hemorrhage and inflammation, it would be reasonable to conclude that he would never willingly stammer again, if it would subject him to a repetition of the operation. Those instances in which the defect is dependant upon mental or moral causes, might possibly be cured by the powerful impression made upon the nervous system, which we know has broken up other morbid states perpetuated by habit. I cannot learn, however, that in this country any surgical operation upon the tongue has resulted in permanent benefit.

Dr. Alfred C. Post, of New York, was the first surgeon in America who performed the operation for the cure of stammering, by dividing the genio-hyo-glossi muscles near their origin. The operation was performed on the 21st May, 1841. Doctor Post has published an account of it in an Appendix to his "*Observations on Strabismus.*"

Dr. Mutter, of Philadelphia, has repeatedly tried the various operations for stammering, including myotomy, acupuncturation, and electropuncture, &c., but without the least benefit, except in those few cases in which there was a positive tongue-tie. In these, myotomy has been useful.

Dr. Pancoast, of the same city, has met with ten cases of true muscular tongue-tie, and in these the division of the genio-glosso-hyoid muscle has been useful in relieving the defect, but in all other cases, surgery has failed to afford benefit.

Dr. Detmold, of New York, having observed, in practising myotomy, the immediate though temporary relaxation of the constricted muscles, on the introduction of the knife, was led to substitute acupuncturation of the tongue, instead of the division of the genio-hyo-glossi muscles, as practised for stammering. He admits that the patients relieved for the moment by his method, very soon relapse and are as bad stammerers as ever. But he is nevertheless of opinion that a frequent repetition of this entirely bloodless, though sometimes very painful operation, will eventually be found to effect a complete cure.—REESE.]

[STAPHYLORAPHY. Dr. J. C. Warren has performed this operation five times since 1820, the date of his first case, and in all but one been completely successful. He claims to be the inventor of the needle with a moveable point, which he employs in these cases.

His son, Dr. John Mason Warren, has operated upon ten cases of fissure, demanding the staphyloplastic operation. In most of them, the fissure existed in both hard and soft palate, extending to the alveolar process, and in one case of a woman thirty years of age, through the jaw and lip. With one exception, all these cases have succeeded to greater or less extent. Where an aperture in the hard palate has remained after the operation, it has been closed by a gold plate.

Dr. Warren's method has been to dissect off the mucous membrane from the hard palate on either side, and stretch this across the fissure, and then unite the edges by sutures. His success has been unparalleled in such examples, for surgical authorities all deny that union even of the soft palate can be effected, when the fissure of the hard palate exceeds an inch. All Dr. Warren's cases disprove this opinion, and his operation may be regarded as peculiar to himself. (See *Autoplastic.*)

Dr. A. H. Stevens, of New York, was the second surgeon in America who performed the operation of staphyloraphy, which he did in 1826, and it will be found mentioned in the N. A. Med. and Surg. Journal, by Dr. Hodge, who was present, and witnessed its success.

Dr. Geo. M'Clellan, of Philadelphia, operated successfully as early as 1823, and has since performed it in two cases of congenital cleft palate, and seven cases of fissures resulting from disease.

Dr. Gibson, of Philadelphia, has been very successful in this operation, and has constructed very ingenious instruments for staphyloraphy, which he has found in practice to afford great facilities to the surgeon, but for the details of his experience I must refer to the last edition of his Institutes and practice of Surgery.

Dr. Mettaner, of Virginia, has published an interesting memoir of staphyloraphy in the American Journal for 1838, and he therein describes his invention of an instrument for the purpose, which he has frequently used since 1830.

Dr. N. R. Smith, of Baltimore, has performed this operation four times, and in two instances with entire success; and Dr. Pancoast, of Philadelphia, has operated twice with the like result.

Dr. Mussey, of Cincinnati, has had complete success in three cases, and partial success in a fourth.

Dr. Alexander E. Hosack, of New York, has published a memoir on staphyloraphy, with cases, and a description of the instruments requisite for the operation. This surgeon has distinguished himself in this department by the number and success of his operations, and his paper on the subject will be found to possess extraordinary merit. Dr. Hosack, after the operation of Staphyloraphy, directs his patients to swallow mucilaginous drinks and nutritious fluids, and finds that the parts concerned are not in the least disturbed, but, on the contrary, the soothing effect of frequently moistening the wound, greatly moderates the inflammation. He maintains that the natural tendency of the cleft palate is to approximate the edges in the act of deglutition, instead of to put the sutures on the stretch, as is generally supposed. It was this approximation of the edges of the fissure in the act of swallowing, which was observed by M. Roux, and first suggested the idea of uniting them by suture, and the same natural tendency exists after the operation as before, and hence there is less danger of the sutures cutting themselves out, if moistened by frequent deglutition of fluids.

The late Dr. George Bushe, of New York, published a work in 1835, upon Cleft Palate, and proposed instruments of his own invention for its cure. He had operated by staphyloraphy with success in a number of cases, and at the time of his lamented death, had attained a high reputation as a surgeon in New York.

Dr. Mott has had great success with this operation in numerous cases, and his assistant, Dr. Carnochan, of New York, has also operated with success.

Dr. Mutter, of Philadelphia, has performed staphyloraphy twelve times, and in the Amer. Journ. of Med. Surg., No. 5, new series, he has published a valuable paper on the subject, describing his instruments, and rendering this operation more simple and easy of performance than by the ordinary method.—REESE.]

[STETHOSCOPE. (From στῆθος, *pectus*, and σκοπεω, *exploro*.) An instrument consisting of a cylinder, originally employed by Laennec, to elucidate the diagnosis of certain diseases of the chest, but now indeed used to throw light on the nature of many other cases. (See *Auscultation*.) "A very few words suffice to state (as Dr. Forbes observes) in what way the stethoscope becomes, in the hands of an expert auscultator, the means of an accurate diagnosis. By it we learn, that the motions of the lungs and heart, in a state of health, produce certain determinate sounds in certain parts of the chest; and that these sounds are modified in certain determinate ways, and certain other determinate sounds superadded in states of disease. By the study of the symptoms during life, by dissection after death, and by considering the principles of the generation of sound, we are able to connect, as cause and effect, particular forms of disease with particular sounds: hence, the indications of the stethoscope, in certain diseases, become positive physical signs of these diseases." (*Cyclopædia of Pract. Med., art Auscultation.*) —C.]

[STRABISMUS. The success of tenotomy in the removal of club-foot, by Dr. Stromeyer, in Germany, and Dr. Detmold in America, led both these gentlemen to suggest the practicability of curing strabismus by the section of the contracted muscles upon which it has been long known to depend.

Mr. Anthony White, of London, demonstrated

its practicability by numerous experiments on inferior animals. But the merit of having first operated for strabismus on the human subject is due to Professor Dieffenbach, of Berlin, which he did successfully in October, 1839.

The following year, hundreds of cases flocked to him from almost every part of the continent, and his success seems to have been commensurate with his opportunities, and in both respects he has probably exceeded any other surgeon in the world. His cases varied from children of five years old to adults of forty, and since his earliest publication on the subject, the operation has been repeated in almost every part of the world, and, for the most part, with gratifying results. Exceptions, it is true, have occurred, in which the deformity has not been removed, and in some cases violent inflammation has followed the operation, disfiguring the patient, and even destroying the eye. In most examples of its failure, however, it will be found that there has been either a lack of discrimination in the adaptation of the operation to the particular variety of strabismus, or a criminal ignorance of surgery on the part of the operator. This must be obvious, when we learn that no such results have followed in any single case of Dieffenbach, notwithstanding they already number some thousands, nor indeed have any such lamentable failures been witnessed among the eminent members of the surgical profession in our own and other countries. Such men have been in the habit of repeating this operation more frequently than any other which deserves the name of surgical, seeing that the number of cases is found far to exceed any estimate heretofore entertained; and no disastrous results have followed, so far as I can learn, from extensive correspondence with those who have extensively practised it, even in a single example. That men who are mere operators, not surgeons, and who aspire to the popular cognomen of eye-doctors, such as that which ignorant pretenders as oculists are wont to assume, should do irreparable mischief to the eye by attempting even this simple operation for the cure of strabismus, is probable and even certain. For the acknowledged simplicity of the operation is such, that these pretenders may occasionally succeed in favourable examples of the deformity, while the patient in such cases experiences a happy *escape*, rather than a *cure*. But as they are incompetent to discriminate between the essentially different varieties of strabismus, depending as it often does on the contraction of entirely different muscles, and requiring an essentially different operation from the ordinary one in many cases; and as such men are incapable of detecting and appreciating the numerous complications of the deformity so often present, it would be marvellous indeed, if in such hands any operation should often succeed. Because the operation is simple, every simpleton in the fraternity has felt at liberty to undertake it, and on his failure he has had the temerity to decry the operation, and quote his own experience in order to bring it into disrepute, thus escaping the censure due to his own incompetence.

Professor Gibson's sentiments on this subject, as well as the estimate that distinguished surgeon places upon the operation, are so well expressed in the last edition of his Institutes of Surgery, that I here transcribe them. Speaking of the mischiefs which have occasionally followed awkward attempts in this department, he says: "These deplorable results are to be traced, no doubt, to the pruritus with which many *physicians* are afflicted to perform such operations as are considered easy, or managed with a modicum of skill: so that persons wholly incompetent, are too often tempted to dash unhesitatingly at what they consider within their reach, and are only convinced by repeated failures, that they have no turn for such exploits. The observation applies not to strabismus only for I well remember, when lithotrity was first announced, how eagerly every tyro in Europe and this country, and even common instrument-makers out of the profession, jumped at the opportunity of displaying their skill; men who never would have dreamed of performing lithotomy or hernia, and whose boldest flights never extended beyond the most insignificant feats of minor surgery." "The time will come, then," adds Professor Gibson, "I have no doubt, when the operation for strabismus will be considered sufficiently delicate and difficult to be worthy the attention of scientific and practical surgeons, and be intrusted to their care, instead of being placed, as it is at this moment, in the hands of unprincipled surgical traders and quacks, whose impositions on the public are bolstered up by patients and puffers, about as ignorant in such matters as the soi-disant operators themselves."

In the same valuable work will be found a communication from the eminent British surgeon, Sir Charles Bell, whose lamented death has so recently thrown a gloom over his numerous admirers all over the world where professional merit is estimated. This paper is fitly entitled by Dr. Gibson, "An interesting Essay on the Philosophy of Strabismus." It may possibly be regarded as one among the latest professional productions of its author's life, and for its philosophical accuracy and practical importance, it is worthy of being perpetuated by being placed in the Institutes of Surgery. When Mr. Cooper's last edition was issued from the press, no one in England had heard of Dieffenbach's success; nor, indeed, had this recent operation for strabismus been then introduced even in Germany. Hence no mention whatever is made of this new illustration of the benefits surgery is conferring upon mankind.

It appears from the Institutes of Surgery, that Professor Gibson attempted the cure of strabismus by dividing the recti muscles of the eye, precisely as now practised some twenty years since in Baltimore. Soon after he repeated it unsuccessfully in Philadelphia in several cases, and was induced to abandon it by the unfavourable opinions expressed on the operation by Dr. Physick. He, however, inculcated the propriety of the operation upon his class many years since, and Dr. A. E. Hosack, of New York, then one of his pupils, distinctly recollects Dr. Gibson's expressions of confidence, that the operation would ultimately succeed.

In America this operation for strabismus has become very common, and thus far the cases have been for the most part successful. Sufficient time has scarcely elapsed, however, in any of them, to decide positively whether the deformity will be permanently relieved, and whether the fears which have been expressed of the effect upon the ultimate action of the other muscles of the eye, may or may not be well founded. Some few instances have been reported, in which the division of the internal rectus

has produced a tendency to eversion of the globe under the action of the antagonist muscle, long after the immediate effects of the operation have ceased. If these fears should be realized, it would be a sad result; but no evidence has yet appeared in this country which would seem to render it probable. On the contrary, in a great multitude of cases, in which this operation has been performed in America, I have not heard of one in which, thus far, either the surgeon or the patient has had any cause to regret it; unless in such instances of failure as were justly ascribable to the ignorance of the mere *operators* into whose hands the patients were unfortunate enough to fall.

Dr. Willard Parker, of New York, claims to be the first surgeon in America who performed this operation, which he did in August, 1840, and with success. Dr. Detmold, of New York, Dr. Goulding, of Arkansas, and Dr. Gross, of Kentucky, soon after repeated it. I regret that I am restricted for want of room, else I should deem it due to Dr. A. C. Post to extract from his work on this subject a portion of the excellent practical remarks with which it abounds. And for the same reason I am prohibited from doing more than to refer the reader to Dr. Gross's valuable paper on Strabismus, published in the *Western Journal of Medicine and Surgery*, for 1842, abounding, as it does, in discriminating criticism upon popular errors on the subject, and furnishing the best statistics on the subject anywhere to be found. Dr. E. H. Dixon, of New York, has also published in the 16th vol. of the *Boston Med. and Surg. Journal*, two papers on the subject, which are meritorious and practical. The experience and success of this surgeon entitle his opinions to respect, but I have space only to make this reference. As, however, Dr. John H. Dix, of Boston, has, in addition to extensive experience in this operation, introduced a method of performing it by subconjunctival section of the muscle, I conclude this article by inserting a brief paper from this gentleman, which, in justice to him, I cannot feel at liberty to abbreviate.

"The operation of dividing the recti muscles for strabismus, as directed by Dieffenbach, was performed by me for the first time, Sept. 9th, 1840. I have since that time operated on 218 eyes of 175 persons, in 43 cases both eyes being operated on. In 14 the strabismus was divergent, in the remainder convergent.

"With regard to the success of the operation, there is great difficulty in giving a correct statistical reply. In very many cases the position of the eye operated on is not permanently decided for eight months, and the relative position of the two eyes may not be for twelve; while more than two-thirds of the subjects reside out of the city, and are lost sight of in a few weeks after the operation.

"If by success is meant an improvement in the position of the eye, a lessening of the squint, every case has been successful. But if by success is meant perfect symmetry in the contour, correctness in the position, and correspondence in the movement of both eyes in every direction, that is, that the eyes shall be in every respect as if they had never squinted, success is rare. But, although, according to this rigid standard, it is rarely found, either among my own patients, or those of other operators, which have fallen under my observations, the result is in a very large proportion of cases so successful, that to an ordinary observer there is no evidence of a squint, or other defect in the eyes. Such, I should say, is the result in three-fourths of the cases; while in the remaining fourth, either the squint is not wholly removed, or the eye acquires a slight inclination in the opposite direction, or else, the position of the eye being good, there is an apparent enlargement of it, rendering it unlike its fellow; or there may be at the inner canthus an unnatural gap or depression, owing to the retraction of the semilunar fold. The difficulty of defining what shall be considered a perfectly successful result, or, as it is popularly termed, a cure of squinting, has been alluded to, and I have been careful in the above statement of the result of my own operations not to exaggerate their success, but would say, in justice to myself, that if those cases only had been taken into the account, which have been operated on for the last seven months, the proportion of imperfect results would be much less, in consequence of adopting a mode of operating different from any hitherto proposed.

"The first step, in the usual methods of operating, is to make midway between the cornea and inner canthus, a long vertical opening in the conjunctiva, by the subsequent retraction of which the semilunar fold may sink back, causing an abrupt indentation at the inner canthus, and giving to the eye on this side the appearance of a globe lying in the orbit, but detached from it; the eye may project, appearing unnaturally large; or it may incline outward, or two or even all of these conditions may combine.

"The subconjunctival division of the muscle, according to the method of M. Guerin, where it is practicable, prevents or materially diminishes these liabilities, and is performed as follows: 'The lids being secured, and the patient in a recumbent position, the eye is everted and kept steady by means of a double hook inserted into the albuginea, and an opening is made through the conjunctiva, and the investing sheath or fascia of the muscle at its lower margin. M. Guerin's knife is now to be passed between the sclerotic and the tendon of the muscle, until it is fairly inserted, when the edge is to be turned outward against the tendon, which sometimes parts with a faint noise.' This is similar to the operation of tenotomy in other parts of the body, but in its application to the muscles of the eye is often objectionable; though it may be adopted without difficulty, when the inversion is slight, the globe prominent, and the patient an adult of sufficient firmness to hold the eye everted with but little aid from the double hook. In order to give to the muscle the degree of tension necessary for the division of its tendon, by simply turning the edge of the knife against it, the double hook must be applied with a force, which, independently of the pain it occasions, might be, though I am not aware that it ever has been, hurtful to the internal textures of the globe, while, from the length of the blade and the rolling of the globe upward, which is prevented only in part by the outward traction with the double hook, the usual motion of cutting is impossible to any useful extent. Unless the curvature of the blade very nearly suits the convexity of the globe, where the division is to be made, as the knife is pressed outward, one portion of the blade may be cutting the conjunctiva before the section of the tendon is thoroughly accomplished. And if it be expedient, as in

very decided cases of squint it is, to divide the muscle posteriorly to its tendon, these difficulties are enhanced. But the more numerous cases of decided squint are precisely those in which it is most important to keep the conjunctiva whole, inasmuch as the greater the squint, the greater the liability to projection of the globe and a gap at the inner canthus.

"I have, therefore, adopted the following method, as far more convenient and effective, and less painful. The patient is sitting with the head inclined slightly backward upon the assistant, who raises the upper lid, and the eye is everted as far as possible by a voluntary effort. A horizontal slit is made, either with a knife or scissors, just above the upper edge of the muscle, through not only the conjunctiva, but the fibro-cellular investment of the muscle. Through this opening the blunt hook is passed between the muscle or tendon and the sclerotic, and carrying it fully down, the lower margin of the muscle will be certainly indicated by the appearance of the end of the hook, covered only by the conjunctiva, in which, at this point, a second horizontal slit, about a line and a half in length, is made. Through this lower slit the section of the muscle or its tendon is made from below upward, with a pair of slightly curved scissors, one blade passing between the conjunctiva and the muscle, and the other between the muscle and the sclerotic; the muscle being at the same time raised a little from the globe, and effectually prevented from rolling upward by the blunt probe or hook, which has been inserted under it from above downward, and is held in the left hand of the operator while he uses the scissors in the right. The section of the muscle is known to be complete, when there is left upon the hook only a strip of conjunctiva; but it may be still further verified by holding this portion of conjunctiva aside, before the hook is withdrawn, so that the sclerotic may be seen or felt. The horizontal openings in the conjunctiva will, in some cases, be found to afford a convenient opportunity of making a free section of indurated and contracted cellular or fibrous tissue, both above and below, a proceeding which, in cases of long standing, is often required; and from the direction of the slits, their edges are brought more nearly in apposition, the greater the change which has taken place in the position of the globe.

"I am fully aware that little credit attaches to those who, following in the track of a great discoverer, strive to appropriate to themselves, by trifling or imaginary improvements, a portion of his reputation, and would by no means be understood to say, that very perfect results have not been obtained in the manner originally directed by Professor Dieffenbach, or that M. Guerin's operation is in all cases impracticable or unsuccessful; but only to express my conviction, that by preserving the integrity of the conjunctiva between the cornea and inner canthus, very important objections to the operation are obviated, and to point out a method by which this may be most easily and thoroughly effected in decided cases. And I am the more convinced that some modification of M. Guerin's method was needed to render it conveniently applicable in decided cases, by the fact that I have searched the foreign journals in vain for evidence of the adoption of the subconjunctival operation by those gentlemen who have made the most valuable communications on the subject of Strabismus.

"In one respect only, the subconjunctival has no advantage over the usual methods. Some cases will occur, in which the division of the internal rectus, as far back as possible, is not followed by a sufficient change in the position of the globe, owing either to the joint action of the oblique muscles, or the inner fibres of the superior and inferior recti, or to the influence of the tunica vaginalis oculi. The division of more than one muscle is seldom, perhaps never expedient, inasmuch as by repeating at intervals of four or six months the division of the same muscle, or rather separating its recent adhesions, a straight position will be gradually attained with less projection of the globe.

When the squint affects both eyes, the two should never be operated on at the same time, and a much longer interval should elapse than is recommended by writers on this subject. Too great haste may result in the eversion of one or both, a result which can be relieved only by dividing the opposite muscle at the expense of an increased projection. I now wait six and twelve months before touching the second eye, which, meanwhile, frequently becomes sufficiently straight, and accordingly the proportion of cases in which both are operated on is much less than formerly.

"The above remarks apply to convergent Strabismus.

"In divergent Strabismus the operation may be considered to be almost invariably and completely successful. I have seen in but one case any sensible projection of the eye. It is, therefore, in this form of strabismus, not important to perform the subconjunctival operation in view of the ultimate result, though by preserving the integrity of the conjunctiva the subsequent inflammation, slight under any circumstances, is still less, and no inconvenience is felt from the temporary fungous growth, which often arises from an extensive vertical section of it."

The following analysis of 50 cases of strabismus has been prepared by Dr. Dix, of Boston, and may serve as indicating the value of the numerical method. It is extracted from his treatise on the subject.

Analysis of 50 cases.

Females	- - -	31
Males	- - - -	19—50
Convergent	- - -	48
Divergent	- - -	2—50
One eye only squinted and was operated on in	- - - -	36
Double, that is, requiring the operation on both eyes	- - -	14—50

Three cases are supposed to have been congenital, and the squint was observed previous to the eighth year in every case except two.

The causes assigned were as follows, viz.: Fits six, Inflammation five, Hooping cough five, Chorea one, Blow two, Fracture of scull one, Imitation eleven, Unknown nineteen.—Reese.]

[STRICTURES IN THE URETHRA. Dr Alfred C. Post, of New York, has published in the New York Journal for 1840, a series of Hospital Reports on this subject which is of great practical value, but my limits will not allow more than this reference to his paper. In one extremely aggravated case, complicated with fistula in perineo, this gentleman adopted the treat-

ment by incision, though in most cases he has succeeded by gradual dilatation.

Professor Dugas, of Georgia, has a paper on the subject of treating strictures by excision in the Southern Med. and Surg. Jour., vol. i. p. 293.

Dr. Alban Goldsmith, of New York, is devoting a large share of attention to the treatment of strictures of the urethra, and has had great success in the employment of iron bougies of a conical shape, upon which he chiefly relies.

Dr. Parker, of New York, reports in the New York Gazette, vol. i. No. 2, 1841, a case illustrating the dangers of employing bougies made of elm bark, which material has been recommended in some of the journals. In this case he was obliged to perform the lateral operation of lithotomy, for the removal of a ball composed of elm bark left in the bladder by the employment of bougies and catheters made of this substance. One such case occurring in a century ought to banish such bougies from practice.—REESE.]

[STRYCHNIA. Its salts, and the extract of nux vomica, have been found useful in paraplegia, amaurosis, some forms of deafness, and a few other paralytic affections, from disease or external injury. The endermic use of strychnia is noticed in the article AMAUROSIS. "Strychnia in all its forms, pure or combined, (says Dr. A. T. Thomson,) is a powerful excitant, displaying its influence, first by an increasing energy of the whole system; and next chiefly on those tracts of the medulla spinalis, which give origin to the motor nerves. The nerves of sensation, however, are also involved in this action; for, along with the muscular contractions and convulsions which supervene, the surface of the body is so morbidly sensitive, as to be sensible of the slightest impressions; even the motion of the air becomes a source of uneasiness, nearly as considerable as in hydrophobic cases." (See *Elem. of Materia Medica, &c.*, p. 186, edit. 2.)—C.]

[STUMPS. P. G. Van Hoorne, in 1803, published a valuable work giving an account of the changes which occur in the texture of stumps after amputation, and particularly in the bone *De lis, quæ in partibus membri præsertim osseis amputatione vulneratis, notanda sunt.* (Lugd. Bat. 1803, 4to.) In the 16th vol. of the *Med. Chir. Trans.*, Mr. Langstaff has published many interesting remarks on the healthy and morbid condition of stumps. According to his investigations, after the effusion and organization of lymph in the healing process, "the absorbents remove such superfluous parts of the muscles, as are likely to retard the progress of cicatrization of the integuments. After this period, the nutrient arteries of the periosteal covering of the divided bone or bones, and the medullary parts, deposite lymph; a medium of cellular tissue is produced, which unites to the organized integumental surface, and these together form a cushion, as a protection to the end of the stump." The absorbents remove the asperities occasioned by the division of the bone; a deposite of osseous matter takes place round its edges, forming a junction with the new bony substance thrown out by the vessels of the medullary texture; and the absorbents, if not interrupted by a diseased state of the stump, produce a regular rounded appearance of the extremity of the bone, in which merely apertures are left for the communication of the nutrient arteries, veins, and nerves of the shaft of the bone, with its coverings.

"Should the surfaces of the amputated part not regularly unite by the first intention, nor by the second, and there be inflammation affecting the divided nerves, then a morbid action is established, which occasions the face of the stump to ulcerate or mortify; frequently causing a portion of the extremity of the bone to project, which occasionally becomes carious, and should be taken off." In other instances, osseous deposite takes place round the edges of the sawn bones in a degree amounting to exostosis; and "sometimes a spiculum of bone projects horizontally, generally taking the direction of the artery, vein, and nerves of the limb, which thus become implicated with the bony deposite; and sometimes (adds Mr. Langstaff) I have found a large spiculum of bone, with a very sharp point, taking an oblique direction, and connected with a muscle, occasioning morbid changes in its fibres, and being a source of great suffering to the patient. In all such stumps, I have invariably found the nerves greatly enlarged at their extremities, giving them a ganglionic appearance, and generally firmly adherent to the surface of the stump, and frequently in union with spicula of bone." On cutting through these bulbous extremities of the nerves, Mr. Langstaff did not notice any marks of enlargement of their natural structure, the thickening appearing to have been occasioned wholly by the deposition of lymph, the effect of inflammation in the cellular tissue covering the neurilema. Mr. Langstaff gives the particulars of numerous preparations and cases in confirmation of his statements. In amputation, he prefers the flap operation to the circular, cutting obliquely through the integuments, muscles, vessels, and nerves, and taking especial care to preserve a sufficient quantity of skin to cover the end of the bone. He notices the bad consequences of leaving too much muscle in the circular operation, in impeding the adhesive process. "If, (says he,) in performing the flap operation, a sufficient quantity of skin be not preserved to cover the stump, and the ends of the nerves are likely to be included, while cicatrization is going on, I should have no hesitation in shortening them by cutting off a portion of each."

The frequent necessity, however, for cutting the large nerves twice, is considered by many surgeons—in which number I wish to be included—as one of the principal objections to flap amputations, more especially of the arm. Thus Sir Charles Bell observes, "Of all the conditions to which man is subject, there is no state of suffering more severe than that produced by the engagement of a nerve in a stump; and therefore I say, that it is most important that the nerve should be directly divided across, and not obliquely torn out. You cannot secure this effect unless you make a free and decided division of the muscles. When you pierce the limb with a great catling knife, and put it close on the bone, and draw it out obliquely, to make the flap, you cut the nerve longer than the other parts. The nerve is firm, but very elastic; it is not so easily cut through as muscles. Being elastic, it goes before the edge of the knife; and, if you look carefully to an amputation performed in this way, you will find that the nerve hangs out, that it becomes necessary to draw it out, and cut it again. What do you say to cutting the nerve a second time, by way of proof that this operation is attended with less pain?" (See *Lond. Med. Gaz.*, vol. xv. p. 95.) In *post mortem* examinations, Molineli and Morgagni long ago found the ends of nerves, which had been cut through, enlarged. Lower and Ar-

nemann noticed the same occurrence in animals, and Proschaska gave an instructive description of such a case.

In Van Hoorne's work are excellent engravings of this condition of the nerves, as well as of the osseous deposition at the end of the bones of stumps, and of necroses in various degrees and stages. In Froriep's *Chir.-Kupfertafelu*, pl. 113, the same things are represented, accompanied by an account of two preparations of stumps, preserved in the museum of the University of Bonn by Professor Mayer, the particulars of which merit the attention of all who are investigating the present subject. Cruveilhier has published a representation of a shoulder-stump, after an amputation performed many years previously by Larrey. The changes in the muscles and ends of the vessels are carefully drawn and explained, as well as the ganglionic enlargement of the nerves. (*Anat. Pathol.*, t. i. livr. vi. pl. 5.—Paris, 1829, 35. Fol.)

In University College Museum is preserved a stump, which, in consequence of bleeding, had been opened on the first night succeeding amputation. Locked jaw ensued; the bone protruded to the extent of an inch; and in six weeks the case ended fatally. The extremity of the sciatic nerve is seen enlarged, and connected to the cicatrix.

When the severe neuralgic affection of a stump, sometimes attended with convulsive twitches, is dependant upon the bulbous enlargement of the end of a nerve, it may sometimes be cured by the repetition of amputation, or even by the mere excision of the extremity of the nerve. The latter operation, I think, with Mr. Mayo, is to be preferred, if the symptoms are clearly attributable to an affection of one nerve. (*Human Pathology*, p. 139.) In support of this advice, Mr. Mayo gives an interesting example of the success of the practice. He likewise adds the particulars of a case, in which the source of the painful affection of the stump was not confined to the cut extremity of the nerve. A second amputation had been performed. "On examining the amputated part, the sciatic nerve and the saphenous nerve were found to terminate in large callous bulbs. In the second operation, care was taken to draw out and remove a considerable portion of the sciatic nerve, which, retracting, lay well covered among the muscles. Nevertheless, when the stump had nearly healed, the old pain again commenced," but was more circumscribed. Mr. Mayo now cut down to the sciatic nerve, where covered by the lower fibres of the glutæus maximus, and divided it. A portion of it was then removed. The benefit was only temporary. Mr. Mayo suspects that amputation at the hip might cure this patient, though loath to recommend this formidable proceeding; and refers to a case in which a neuralgia, which had followed an amputation above the wrist, had returned after a second amputation, but been permanently cured by amputation of the shoulder. Sometimes the relief afforded by excision of the bulb of the nerve is not complete, as we find exemplified in the case under Mr. Palmer, who removed from a stump a portion of the fibular nerve. "The stump is still occasionally agitated by slight spasms, and the nerve, for above two inches above the cicatrix, (as may be perceived by feeling through the integuments,) is still enlarged and very sensitive. Unquestionably the relief afforded has been immense; but I now regret that I did not in the first place remove a greater length of the nerve, so as completely to obviate the possibility of its being again involved in the new cicatrix." (*Palmer*, in *Lond. Med Gaz.*, vol. xvii. p. 220.)

When the soft parts are deficient, and the bone prominent on the face of the stump, forcible attempts are often made to bring the integuments together by adhesive straps. These endeavours (as Mr. James correctly observes) commonly fail, and are indeed mischievous; for, if the straps are brought over the surface of the bone, then they bind down this thin and irritable covering upon a broad surface, which is sure to indispose them to unite; and, if applied at the sides, although they may bring the edges together, yet they will force the soft parts still more back than the bone. The only remedy for such stumps, according to Mr. James, is to be found in the skilful application of a bandage, and a proper position; and these failing, in sawing off the bone higher up. (See *Provincial Med. and Surgical Trans.*, vol. iii. p. 228.)

Mr. Benjamin Phillips has written some good remarks on inflammation of the medullary membrane succeeding to amputation; one of the most serious, and, as it appears to this gentleman, not the least frequent of the accidents which follow its operation. It is from this cause that necrosis of the whole thickness of the sawn bone mostly arises. The several stages of the case are well described by Mr. Phillips, as that of simple congestion of the medullary membrane; another, leading to osseous deposite; a third, attended with the formation of pus; and a fourth, with gangrene of the texture in question. Mr. Phillips ascribes the disorder to the violence inflicted upon it by the saw. An anxiety, he observes, is felt to prevent such action of the saw upon the periosteum; "but the action of the instrument upon this membrane would not bring about those formidable consequences, with which such injuries to the medullary membrane are pregnant." He notices the custom, followed in many parts of the continent, of applying a very tight bandage round the stump, for the purpose of preventing the retraction of the muscles. This system, he states, exists at La Charité in Paris, where the proportion of unfortunate terminations in cases of amputation is very great. Dr. Carswell thinks it probable, that the tight bandages there used produce congestion, and a tendency to inflammation of the medullary texture of the sawn bones. (*B. Phillips*, in *Lond. Med. Gaz.*, vol. xiii. p. 189, &c.)

When the end of the femur, tibia, or other bone of a stump, is affected with necrosis of its whole thickness, and this for some extent, the excision and removal of the sequestrum is the most expeditious means of cure.—C.]

[SUTURES. For the few operations in which the twisted suture is still retained in practice, the common pin, preferred by Velpeau to that made of steel, silver, or gold, has been generally introduced into this country. The objection to steel, that it so soon oxydizes, is not remedied by gilding them, as experience proves. When silver or gold is used, they become too thick when the steel points are applied, and they are not firm enough to use without them. Dr. Eve, who has employed the common pin, informs me that he has known it to remain ten days beneath a varicose vein, and yet continue as bright as ever. Velpeau prefers the common pin in all cases of operations upon the veins, where it is so important to avoid inflammation.

Dr. E. H. Dixon, of New York, has devised a novel form of needles for passing the interrupted suture in deep seated wounds, and adapted also to staphyloraphy. I regret that my limited space will permit me only to refer to the 25th vol. of the Boston Med. and Surg. Journal for a description of the invention.—REESE.]

T.

[TENOTOMY. The name given to the division of tendons for the removal of deformities dependant upon a loss of equilibrium in the antagonism of corresponding muscles, as recently practised by Stromeyer and Dieffenbach, in Germany, and within a few years adopted throughout the surgical world. The tendons which have been divided by surgeons within a few years past for wry neck, strabismus, club-foot, and other deformities are very numerous, and I must content myself with a mere catalogue of the muscles whose tendons have been subjected to division in America, referring to the several articles in this Appendix for further and detailed information. The sterno-cleido-mastoideus; tendo Achilles; tibialis anticus and posticus; peroneus; flexor longus pollicis pedis; the extensors of the toes; the flexors of the toes; the semimembranosus; the semitendinosus; the gracilis; the sartorius; the adductor longus; the tensor vaginæ femoris; the fascia lata; the plantar fascia; the masseter; the biceps brachii; flexor carpi radialis; flexor carpi ulnaris; palmaris longus; flexor digitorum manus sublimis; flexors of the fingers; pectineus; biceps femoris, genio-hyo-glossus; rectus internus and externus oculi; superior and inferior rectus; superior and inferior oblique, besides a great variety of the fasciæ and aponeuroses of the limbs. All these tendons have been divided subcutaneously, a measure which is found not only to make the operation almost bloodless, but which, at the same time, avoids subsequent inflammation, and greatly facilitates recovery. (See WRY-NECK, and other examples of orthopœdic surgery.)—REESE.]

[TESTICLE, DISEASES OF THE. Sir Astley Cooper believes, that the body of the testicle is less prone to disease than the gland of the breast; but acknowledges that it is often the seat of disease, and that the spermatic cord, and the coats of the testicle, are subject to a great variety of diseases. Among the circumstances which appear to him to offer some explanation of the frequency of diseases of the testicles, are the following: 1. Their pendulous situation, which renders them very liable to inflammation; for the blood gravitates into them, and returns with difficulty by the veins. 2. The excitement to which they are liable from passion, and which, often not admitting of being immediately gratified, leads to an accumulation of seminal secretion, and to a painful and excessive distention of the seminiferous tubes, followed by inflammation. 3. The testicles are greatly exposed to blows and pressure. 4. They are frequently involved, secondarily, in consequence of diseases of the urethra and prostate gland. 5. The changes which the testicle undergoes in old age, and at puberty, sometimes bring on disease of it. 6. The liability of the testicle to be prevented, or interrupted, in its descent into the scrotum. This movement, though usually completed before birth, is often delayed for years, and the testicle may then remain at the lower part of the abdomen, or in the groin; in which last situation it is much exposed to injury. (See *Sir A. Cooper, On the Structure and Diseases of the Testis*, part 2, p. 5.)

The diseases in which this organ is concerned, conveniently admit of being referred to four heads: diseases of the testis; of the tunica vaginalis; of the cord; and of the scrotum. The reader will find an account of the three last classes of diseases in the articles HYDROCELE, HÆMATOCELE, SCROTUM, and VARICOCELE, so that these subjects will not require particular notice in this place.

It would perhaps be difficult to cite any department of surgery in which greater improvement has been made, within the last twenty years, than in that which relates to the discrimination and more judicious practice adopted with regard to diseases of the testicle. The result is, that castration, which at one period used to be performed every week, and sometimes two or three times a week in the hospitals of London, is now a comparatively rare proceeding. The same beneficial reform appears, from the testimony of Dupuytren, to have been also made in France, where, he observes, that the love of operating, without any kind of true occasion for the measure, was formerly never more conspicuously exemplified than in cases of enlarged testicles. But, says he, at the present day, about a hundred patients are annually admitted into the Hôtel-Dieu for such diseases, most of whom are cured, and stand in no need of being operated upon. In the majority of instances, Dupuytren ascertained, that the enlargement of the testicles proceeds from external violence, syphilis of long standing, or from scrofulous or some other unfavourable state of the general health; and hence he made it a rule never to resort to castration, without having first tried, for a full month or six weeks, some method of treatment adapted to the cause of the complaint. (See *Dupuytren*, in *Clin. Chir.*, t. i. p. 86—88.)

Acute Inflammation of the Testicle; Orchitis, (from ὀρχις, a testicle,) or *hernia humeralis*, an absurd but common name for the complaint, more especially when it arises from irritation in the urethra, whether excited by gonorrhœa, injections, bougies, or strictures. This last expression being founded, as Sir Astley Cooper justly observes, upon mistaken pathological principles, it ought to be renounced. When acute inflammation of the testicle arises from sympathy with the urethra, the first symptom is an irritation in the membranous or prostatic portion of that canal, succeeded by tenderness in the spermatic cord, and swelling and pain in the epididymis. The swelling perhaps is generally first noticed in the latter part, the testicle next swells, soon increasing to two or three times its natural size, and becoming so tender that the pressure of the thigh on it can scarcely be endured. Its weight being also increased, it draws the spermatic cord painfully downwards; and, in this state, the patient obtains some re-

thef by supporting the part with his hands. The pain is obtuse, resembling the suffering caused by squeezing the testicle. The pain and swelling extend along the spermatic cord into the inguinal canal, and great uneasiness is experienced in the groin, hip, inner part of the thigh, and especially the loins, in consequence of the origin of the spermatic nerves from the lumbar. "From the communication between the renal and spermatic nerves, with the nerves of the stomach by the solar plexus, and with those of the intestines through the mesenteric plexus, the stomach is affected with nausea, and sometimes severe vomiting," and pain in the intestines and obstinate constipation are usually experienced. (*Sir Astley Cooper, Op.* cit., part 2, p. 8.)

Although the testicle is so augmented in size, that the rugæ of the scrotum are effaced, it still retains its originally oval form, being rounded at its fore-part, but somewhat flattened at its sides; and it feels exceedingly hard. The scrotum, the rugæ of which are obliterated by the distention, presents a smooth appearance, and is redder than natural; and, as serum is effused in its cellular tissue, it often pits on pressure. Its veins are quite turgid and prominent, and, if punctured, bleed very freely. With reference to its original dimensions, the epididymis always swells more than the testicle itself; which Sir Astley Cooper ascribes to the covering of the former part being less compact. The epididymis remains also longer swollen than the testicle, the globus major and minor being more enlarged than its body, and the swelling of the first generally very perceptible in front of the spermatic cord. The pressure made by the tendon of the external oblique on the swollen cord is the occasion of severe pain, which sometimes undergoes severe exacerbations from spasms of the cremaster.

During the violence of the inflammation, the constitution is often greatly disturbed; the tongue becoming furred, the pulse quick and hard, the skin hot, the bowels confined, and blood, taken from the arm, presenting a buffy and cupped appearance. It is an observation, made by Sir Astley Cooper, that when acute inflammation of the testicle arises from sympathy with the urethra, it rarely proceeds to suppuration; but when it is the effect of a blow, or of vicissitude of temperature, suppuration sometimes, though not frequently, follows; and then all the symptoms are aggravated, and shiverings added to those already described. In fact, the purulent matter being confined by the fibrous covering of the albuginea, a texture that ulcerates with difficulty, much time elapses before the abscess bursts; and when this happens, several openings and sinuses are frequently formed, which discharge both pus and seminal fluid, and are difficult to heal. (*Sir Astley Cooper, Op.* cit., p. 10—12.)

I once attended a soldier, with acute inflammation of the testicle, in the Military Hospital of Canterbury, who experienced so much pain in the abdomen on the fifth day of the attack, accompanied by vast swelling of the cord, almost incessant vomiting, complete and obstinate stoppage of the stools, and severe constitutional disturbance, that a suspicion of hernia was raised. The absence of tension in the abdomen, the limitation of the pain to one side of the belly, the inability of feeling anything like the testicle of its ordinary size below the tumour, as in a bubonocele, and the history, which made it impossible that the case could be a congenital hernia, were circumstances, which prevented an erroneous view of the complaint from being adopted. "But, (as Sir Astley Cooper observes,) if a hernia had existed on the side in which a blow has been received, and the patient has a swelling attended with exquisite pain, sickness, and vomiting, redness of the scrotum, or even a purple appearance of it, constipation, of two or three days continuance, with tenderness of the abdomen, then great caution will be required in forming a judgment of its nature, and in determining on its treatment. It will be best to give a purgative injection immediately, as well as an aperient medicine; and free evacuation from the intestines will determine the question. The swelling will be harder than hernia, its form different, and there will be a greater pain in the part." (*Op.* cit., p. 13.)

With respect to the causes of acute inflammation of the testicle, the greater number of examples of it unquestionably arise from irritation in the urethra, especially its prostatic and membranous portions. In the early stage of gonorrhœa, inflammation of the testis rarely occurs, but between the tenth and twenty-first days, it frequently takes place. Sir Astley Cooper's investigations lead him to believe, that it happens in consequence of the verumontanum, and termination of the seminal ducts, becoming irritated, and the inflammation extending along the interior of the vas deferens to the testicle. (*Op.* cit., p. 15.) When inflammation of the testicle comes on in gonorrhœa, the urethral discharge generally stops, or undergoes a considerable diminution, so that it appears to some pathologists as if there were a translation of the inflammation from the urethra to the testicle; a view to which Sir Benjamin Brodie inclines, and which is entirely different from the other, to which I have been adverting. He admits, however, that "inflammation of the testicle seems to be sometimes independent of the translation of the inflammation, or of the suppression of the discharge from the urethra; and it must then be attributed to the extension of the inflammation of the urethra and vasa deferentia to the testicle." (See *Lond. Med. Gaz.*, vol. xiii. p. 218.)

By many surgeons the employment of injections for the cure of gonorrhœa, is regarded as a frequent cause of inflammation of the testicle. If they be used, Sir Astley Cooper is of opinion that the patient should be directed to compress the urethra two inches from its orifice, so as to prevent the fluid from passing beyond that point, and towards the membranous and prostatic portions of it.

It is well known to every surgeon of experience, that the irritation of the urethra with bougies, or catheters, often brings on inflammation of the testicle; but, according to Sir Astley Cooper's observations, this rarely happens, except when the instrument is passed beyond three or four inches. Any injury (he adds) of the prostate gland may have the same effect, as is sometimes noticed after lithotomy. "The prostate gland, which seems almost a concomitant of age, is sometimes accompanied with inflammation of the testis. Inflammation in the neck of the bladder produces this disease; and a calculus in the bladder, pressing upon the orifice of the urethra, has been known to occasion it, although it generally produces only a spasm of the cremaster muscle. A blow upon the testis is a frequent cause; and, if it be severe, it

produces vomiting at the instant." (*Sir A. Cooper, Op.* cit., p. 18.)

The same distinguished surgeon has remarked, that "a wound of the testis does not produce the pain and inflammatory effects which might be anticipated; for (says he) I have several times known a lancet, and even a trocar, thrust into its substance. It is followed by a sickening pain, and the patient sometimes vomits; but the wound heals readily, and without suppuration. In one case, however, in which the trocar was twice thrust into a testis, violent inflammation and suppuration succeeded." (*Op.* cit., p. 19.) The testicle, not yet descended into the scrotum, may inflame from blows, or the pressure of a truss; and give rise to excessive pain, vomiting, constipation, tenderness in the abdomen, and severe febrile disturbance.

Acute inflammation of the testicle often produces a considerable effusion of serous fluid in the cavity of the tunica vaginalis; but, on the subsidence of the inflammation, this kind of hydrocele is absorbed. Another effect, noticed by Sir Astley Cooper, is adhesion and thickening of the above membrane, which effects sometimes remain a good while, and may be mistaken for a disease of the testicle itself. The adhesion of one portion of the tunica vaginalis to the other may be either partial or complete. The epididymis also swells, sometimes at its lower, and sometimes at its upper part. When such swelling is at the lower, it is believed by Sir Astley Cooper to be situated in the cellular tissue of the vas deferens, where it forms its first convolutions; and frequently it does not depend upon any effusion in the interior of the duct, and consequently the function of the testis continues perfect. When the swelling occupies the upper part of the epididymis, or its globus major, adhesive matter is effused into the cellular tissue, "between the coni vasculosi, at their termination in the epididymis; and sometimes a sac, containing a mucilaginous fluid, is found in this part. This portion of the epididymis is more frequently diseased than any other part of it, or the testis; but the result is less important than in other parts, because some of the vasa efferentia and coni vasculosi still carry the semen from the testicle to the epididymis. The coni vasculosi, under this state of disease, are thickened, hardened, and of a dark brown colour." Sir Astley Cooper possesses also a preparation, in which, after inflammation, a tumour, somewhat larger than a pea, was seated amidst the seminiferous tubes, surrounded by an exceedingly vascular surface. In general (says he) I observe, that where there are marks of inflammation upon the tunics of the testis, such as adhesions, the substance of the gland itself is changed, the septa are much more apparent than usual, the number of the seminiferous tubes is diminished, and their size so reduced, that many are converted from tubes into mere cords. (*Sir Astley Cooper, Op.* cit., p. 21.)

The induration left after inflammation of the testicle, is described by Sir Benjamin Brodie as dependant upon effusion of lymph into the interstices of the glandular structure, and as not producing any permanent injury of the functions of the organ. In six or twelve months, the hardness disappears: "but," he adds, "there are a few cases, in which the inflammation is so severe, as actually to injure some portion of the glandular structure. I examined the body of a gentleman, who had had inflammation of the testicle from a gonorrhœa twenty years before. The testicle, which had been inflamed, was from that time smaller than the other, and a part of it remained considerably indurated. I knew these facts previously, and I was curious to examine the state of the testicle by dissection. On making a section of it, I found that about two thirds of the tubuli testis remained in their natural condition, while the remainder had become converted into a white substance, having the consistence, but not the fibrous structure, of ligament." (See *Lond. Med. Gaz.*, vol. xiii. p. 219.)

Atrophy, or a wasting away of the testicle, which is an occasional consequence of inflammation of it, is observed by Sir Astley Cooper to take place more frequently at puberty than any other age. A person receives a blow on the part, or the testicle inflames spontaneously; or, more rarely, the atrophy follows hernia humoralis from gonorrhœa. The change consists in an absorption of the whole of the glandular structure, the tunica vaginalis being left adherent to the tunica albuginea, with the septa within the latter. In a wasted testicle at St. Thomas's Hospital, quicksilver descended in the vas deferens only about half way between the abdominal ring and the epididymis. (*Sir Astley Cooper, Op.* cit., p. 24.) A patient with acute inflammation of the testicle should wear a suspensory, and keep himself quiet on a sofa, or even in bed, in the recumbent position. Leeches should be applied to the scrotum, and, if the local and general symptoms be severe, it may be necessary to take blood from the arm, or from the loins by cupping. When leeches cannot be obtained, the surgeon may puncture three or four veins of the scrotum, with the point of the lancet introduced transversely with respect to these vessels, which will then bleed freely, more especially if the parts be placed in warm water.

The recumbent position does not obviate the necessity for supporting the testicle with a suspensory bandage, or handkerchief; and, as Sir Astley Cooper remarks, the inflamed part should thus be brought towards the abdomen, and not suffered to fall between the thighs, which would destroy the salutary influence of the recumbent posture. The suspensory bandage should have four tapes: two in front and two behind. "The two anterior are carried to the loins, which they cross, and are tied on the forepart of the abdomen; whilst the two behind ought to be brought up to the forepart of the groin upon each side, and should be fastened to those which surround the abdomen. Thus a real support is given; but if the hinder tapes are carried between the thighs to the loins, as they usually are, the testicles are painfully drawn back, rather than supported." (*Sir Astley Cooper, Op.* cit., p. 25.) When the patient has not a regular suspensory bandage, he may support the part very well with a handkerchief, which may be fastened at each end to another handkerchief, or band, placed round the loins; or a handkerchief may be "doubled in a triangular form, and a piece of tape attached to the middle of its base, and carried between the thighs to the back, where two of the ends of the handkerchief are to be tied, whilst the third angle is brought forward and upwards before the scrotum." (*Op.* cit., p. 26.)

With respect to local applications, cold ones frequently answer best, when the pain is not very severe; but, in other instances, fomentations and poultices are generally preferable

When leeches are used, it is an excellent plan, after they drop off, to apply a poultice, into which the bites will still continue to bleed for some time very freely, without any occasion for the surgeon or patient to take further trouble to promote the hemorrhage. Warm emollient applications are supposed to act beneficially by their relaxing effect on the textures covering the swollen testicle.

In addition to the foregoing means, the bowels should be kept open with antimonial saline purgatives; and, during the prevalence of severe pain, or great nervous irritation, eight or ten grains of the compound powder of ipecacuanha, or half a grain of the muriate or acetate of morphia, should be given every evening.

The liquor plumbi subacetatis dilutus, with or without a small quantity of spirit of wine added to it; or the liquor ammon. acet., if no leech-bites are present; or a solution of one drachm of the muriate of ammonia in a pint of water, are all of them applications in common use, when cold ones are judged advantageous. Unless the inflammation yield quickly, the local bleeding must be repeated, and even in some cases venesection. Emetics and nauseating doses of tartrate of antimony are occasionally resorted to. Mr. Hunter states, that he has known a vomit remove the swelling almost instantaneously. "The effects of the vomit most probably arise from the sympathy between the stomach and the testicle." (*On the Venereal Disease*, p. 91.) Sir Astley Cooper notices certain irritable constitutions, in which the continuance of depletion will not succeed; here, says he, "the best practice, when the pulse is jerking, the patient irritable, and the part painful, is to give the submuriate of mercury with pulvis ipecacuanhæ comp."

If suppuration occur, fomentations and poultices are to be applied; and, as soon as the matter can be perceived, it should be discharged, as otherwise the secreting substance of the testis is destroyed, and several openings, instead of one, are produced. (*Sir Astley Cooper, Op.* cit., p. 30.)

It is generally a long time before the swelling of the testicle entirely subsides; previously to its becoming less, it usually becomes softer. "It is still much longer, (as Mr. Hunter observes,) sometimes even years, before the epididymis returns to its natural state; sometimes it is never reduced to its natural size and softness; however, this is not of much consequence, as no great inconvenience results from the continuance of the hardness simply, though sometimes, perhaps, such testicles are rendered totally useless. I never had an opportunity of examining the testicle of one that was known to have this complaint; but have examined testicles where the epididymis has had the same external feel, and where the canal of the vas deferens has been obliterated. But this I suspect seldom happens; for there are people who have both testicles swelled, and, notwithstanding, discharge their semen as before. It is in this stage of the complaint, that resolvents may be of service, such as mercurial friction joined with camphor." (*Hunter on the Ven. Disease*, p. 92.) Ointments, containing the hydriodate of potash, are also now sometimes employed with the view of dispersing the induration; so likewise are poultices composed of vinegar and oatmeal; the emplastrum ammon. cum hydrargyro; or a lotion, consisting of muriate of ammonia and vinegar, mixed with bread. A suspensory bandage lined with oil-silk, is recommended by Sir Astley Cooper as an excellent application. He combines with local means constitutional treatment, as small doses of the bichloride of mercury, or pil. hydrarg. gr. ij., ant. tart. gr. ¼, or extract colocynth. comp. gr. iij., with ipecacuanh. gr. ij. made into a pill, and taken every night. If nausea be excited, this he deems advantageous. He speaks also favourably of the effects of the liquor potassæ, the pil. hydrarg. chloridi comp., and the tincture of iodine, its effects being carefully watched.

In cynanche parotidea, there is occasionlly a transfer of the inflammation to the testicle; a case requiring the exhibition of liq. ammon. acet., with sulphate of magnesia, or the saline mixture with tartarized antimony, and a pill, containing calomel and antimonial powder. Leeches, with a poultice, or cold lotion, are also proper. (*Sir Astley Cooper, Op.* cit., p. 78.)

The *granular swelling of the testicle*, as it is termed, is a protrusion of granulations from an abscess either of the epididymis or testis, and may be the result of acute or chronic inflammation. The granulations, as they arise, being compressed by the unyielding nature of the tunica albuginea, protrude through the ulcerated opening in it, and form a swelling, which often projects through the scrotum. This disease has received the names of *lipoma* and *fungus testis*, but very improperly, as it consists neither of a fatty substance, nor of a real fungus. Sir Benjamin Brodie gives the following account of it, as an occasional consequence of chronic inflammation of the testicle. "The testicle becomes adherent to the skin at one part, and here the skin inflames and ulcerates; and then a fungus, of small size at first, protrudes through the ulcerated opening, but gradually becomes larger afterwards; and, on the surface of this fungus, you find some of the same kind of yellow substance which is within the testicle itself. What is called a fungus, however, is not a fungus in reality, but the glandular structure of the testis itself." The same experienced surgeon joins Sir Astley Cooper in comparing its formation to that of hernia cerebri, following ulceration of the dura mater. "If (says the former) you dissect the parts in this stage of the disease, you will find, not only that the skin has ulcerated, but that the tunica vaginalis and the tunica albuginea have ulcerated also; and that the glandular structure of the testicle projects through all these openings. You may ascertain the same thing in the living person; for, when the fungus is large, no portion of the testicle remains within the scrotum, and you may distinctly trace the spermatic cord into the centre of the fungus. There are a few cases in which an abscess forms in the substance of the testicle, and bursts externally, without the protrusion of a fungus; but these are comparatively rare. The inner surface of such an abscess secretes the yellow substance which I have described; and you will find large masses of it, with a laminated structure, coming out of the cavity of the abscess. The disease, if it be arrested in the early stage, leaves the testicle with the glandular structure not at all impaired. If it be arrested after it has advanced some way, the glandular structure is partially destroyed; but if it be allowed to run its course, the whole of the glandular structure disappears; and you find in lieu of it a new-formed white organized

substance, having the consistence of ligament, but without its fibrous character." In the early stage, the testicle is enlarged to many times its natural size; but, when the disease is suffered to proceed, the large testicle disappears, and merely a knob or tubercle is left, connected with the slender remains of the spermatic cord. (*Sir Benjamin Brodie*, in *Lond. Med. Gaz.*, vol. xiii. p. 221.)

This disease was briefly noticed by me in an early edition of another publication, and described as "a particular affection of the testicle, in which a fungus grows from the glandular substance of this body, and, in some instances, from the surface of the tunica albuginea. The excrescence is usually preceded by an enlargement of the testicle, in consequence of a bruise, or some species of external violence. A small abscess takes place, and bursts, and from the ulcerated opening the fungus gradually protrudes." I then proceeded to represent how unnecessary and improper it was to extirpate the testicle, on account of this affection, and recommended the fungus to be cut off, or else destroyed with caustic. I founded my advice on a successful attempt of the first kind, which was made in St. Bartholomew's Hospital, by Sir James Earle, a little while before my book was published. (See *First Lines of the Practice of Surgery*, p. 399.)

An interesting paper was written on the subject by my friend Mr. Lawrence, who favoured the public with a more particular account, and nine cases illustrative of the causes, symptoms, and progress of the disorder. The patient generally assigns some blow, or other injury, as the cause of the complaint; in other instances, it originates in consequence of hernia humoralis from gonorrhœa, and sometimes appears spontaneously. A painful swelling of the gland, particularly characterized by its hardness, is the first appearance of the disease. After a certain length of time, the scrotum, growing gradually thinner, ulcerates; but the opening which is thus formed, instead of discharging matter, gives issue to a firm, and generally insensible fungus. The surrounding integuments and cellular substance are thickened and indurated by the complaint, so that there appears to be altogether a considerable mass of disease. The pain abates, and the swelling subsides considerably, when the scrotum has given way. In this state, the disorder appears very indolent; but if the fungus be destroyed by any means, the integuments come together, and a cicatrix ensues, which is inseparably connected with the testicle. Mr. Lawrence observes, that if the part be examined while the fungus still remains, the excrescence is found to have its origin in the glandular substance of the testicle itself; that the coats of the part are destroyed to a certain extent; and that a protrusion of the tubuli seminiferi takes place through the aperture thus formed. Mr. Lawrence has ascertained the continuity of the excrescence with the pulpy substance of the testicle, of which more or less remains, according to the difference in the period of the disorder. He thinks that the glandular part of the testicle experiences an inflammatory affection in the first instance, in consequence of the violence inflicted on it; and that the confinement of the swollen substance, by the dense and unyielding tunica albuginea, sufficiently explains the peculiar hardness of the tumour, and the pain which is always attendant on this stage of the disorder. The absorption of the coats of the testis, and of the scrotum, obviates the tension of the parts, and thereby restores ease to the patient, at the same time that the fungus makes its appearance externally.

The excrescence may be removed with a knife, or, if the nature of its attachment permit, with a ligature, or it may be destroyed with escharotic applications. Mr. Lawrence gives the preference to removing the tumour to a level with the scrotum, by means of the knife, as the most expeditious and effectual mode of treatment. He can discern no ground whatever for proposing castration in this complaint, since, in no part of its progress, nor in any of its possible consequences and effects, can it expose the patient to the slightest risk. I remember the time, however, when the testicle was often removed on account of this disease. But no surgeon of the present day would ever think of such a proceeding.

Mr. Lawrence also mentions the possibility of there being other kinds of fungi, which grow from the testicle, and quotes an instance, in which Dr. Macartney found a fungus, of a firm and dense structure, growing from the tunica albuginea, while all the substance of the testicle itself was sound. Dr. Macartney was so kind as to show me the preparation, affording a clear specimen of the second kind of fungus. (See *Edin. Med. and Surg. Journal for July*, 1808.) Callisen represents the excrescence as sometimes originating from the surface of the tunica vaginalis.

Sir Benjamin Brodie, instead of cutting away the protruding mass, which he deems objectionable, on account of the tubuli testis being thus sliced away, keeps the patient in the recumbent posture in bed; gives him mercury; sprinkles the projecting substance every day with finely levigated nitric oxyde of mercury, and applies over this simple dressing. Under such treatment, the surface soon becomes covered with red healthy granulations. Then lint, dipped in a weak solution of copper in camphor mixture, may be used as a dressing.

The reader will discern some discrepance in the accounts given of this disease by different writers, some representing the substance as consisting of fungous granulations; and others as being actually a protrusion of the glandular substance of the testicle itself. I should say, that both forms of disease occur, but that they should not be confounded together.

Chronic Inflammation, or Enlargement of the Testicle.—Sir Astley Cooper adverts to the frequency of this disease, and to its being sometimes mistaken for one of a malignant nature. "It begins (says he) with a hardness and swelling of the epididymis, is at first unattended with pain, and is discovered by accident after it has acquired a considerable bulk." The testicle at length becomes involved, the form of the epididymis is preserved, although its size is augmented; and its separation from the testicle may still be distinctly traced. The latter, when enlarged and hardened, generally retains its natural smoothness, but its form is rounder than natural; frequently, a clear transparent serous fluid is effused in the tunica vaginalis, making one of the cases to which the term *hydro-sarcocele* is applied. "Each epididymis and testicle is frequently contemporaneously affected; and hydrocele often exists, on one side, but not on the

other; yet sometimes on both sides. One testis may cease to swell, and the other then becomes enlarged. The testicle and epididymis continue smooth under great increase, and the spermatic cord is not usually hardened, but its veins are a little swollen, and it is consequently somewhat increased in size. When the enlargement in the testis and epididymis is considerable, slight pain and a sense of weight are complained of in the loins and thighs." The disease may remain in this state for months, requiring merely to be supported; but from catarrh, a slight blow in riding, some indiscretion in drinking, or other excess, the swelling is disposed to increase, attended with great pain in the part and loins, and swelling and redness of the scrotum. These inconveniences are relieved by leeches and purgatives; but, in a few weeks, on the patient again taking exercise, and returning to his usual mode of living, the disease is once more suddenly augmented. The repetition of such attacks at length makes the patient anxious to have the part removed. In the course of time an abscess forms, denoted by an obscure fluctuation; and, if punctured, a thick pus of bad quality is discharged. When the abscess is formed in the body of the testis, the tunica albuginea greatly retards the progress of the matter to the surface.

According to Cruveilhier, the body of the testicle is affected only consecutively; "and then (says he) either the tubercular infiltration takes place along the fibrous radiating prolongations, which, proceeding from the corpus Highmorianum, penetrate the substance of the testicle; or else tubercles, more or less numerously, form at different points of the texture of that organ." (*Cruveilhier, Anat. Pathol.*, livr. ix.)

Sir Benjamin Brodie represents the testicle as being at first somewhat knobby and irregular; but, as it increases in size, and becomes harder, the different knobs seem to run into one another, and, at last, the part constitutes one large, hard, uniform oval swelling. He admits that the disease generally commences in the epididymis, but not always. (See *Lond. Med. Gaz.*, vol. xiii. p. 220.)

In the dissection of a testicle thus affected, a yellow unorganized matter is found collected in small masses in its glandular structure; and, in a more advanced stage of the disease, these masses are larger in certain places; while, in others, the glandular structure retains its natural appearance. All this is well represented in Cruveilhier's 9th *Livraison*, pl. 1. In a still more advanced stage, the yellow deposite forms distinct hard masses, and generally more or less laminated. (*Sir B. Brodie.*) Dupuytren also describes the tubercular degeneration as one of the principal characters of the disease; and he states that, in most instances, it affects the fibrocellular tissue around the epididymis, and also the substance of the testicle itself. (*Clin. Chir.*, t. i. p. 101.) Cruveilhier, who has published an accurate description of it, illustrated by plates, regards it as the result of chronic inflammation of the epididymis. (*Anat. Pathol.*, livr. ix. pl. 1.) In what Sir Astley Cooper terms the adhesive stage, the testicle and epididymis, when dissected, have a general yellowish appearance, and considerable solidity. "When (says he) I make a section of a chronic enlargement of the testis, throw it into water, and agitate it, a whitish yellow fluid proceeds from the seminiferous tubes, which are extremely dilated, and then appear emptied. But still the same bulk of the testicle remains, owing to the cellular membrane of the part being loaded with a yellow fibrine; the rete is filled with the same secretion as the tubuli; the epididymis is similarly diseased; and sometimes the vesiculæ seminales and vasa deferentia are distended with a similar deposite. Cruveilhier gives one example, in which all these parts, and also the ejaculator ducts, and prostate gland, contained tubercular matter. Sometimes abscess and ulceration are met with, and in this case a part of the testicle is destroyed, and the complete recovery of its functions is impossible. Occasionally sinuses lead into these abscesses, the cavities and outlets of which, still secreting semen, are prevented from closing till the secreting surface be healed or destroyed. (*Sir A. Cooper, Op.* cit., p. 37.) The protrusion of high granulations from such abscesses, and termed the *granular testicle*, I have already noticed. Chronic inflammation of the testicle sometimes comes on as a consequence of local injury; but much more frequently as the result of some constitutional derangement, as that from syphilis or rheumatism. (See *Dupuytren, Clin. Chir.*, t. i. p. 88; *Sir B. Brodie, &c.*) According to Sir Astley Cooper, it often takes place in persons who have been scrofulous in their youth. (Also *Dupuytren*, vol. cit., p. 100.) It is frequently the product of a constitution worn and broken by intemperance. It often follows a long course of mercury; and "it arises in habits in which the vital powers are diminished, and in which we often find sloughing of the cellular membrane in the form of chronic carbuncle. Frequent exposure to wet, cold, or fatigue, and an excessive indulgence of the passions, also dispose to its production. The most frequent occasional cause is urethral disease." (*Sir Astley Cooper, Op.* cit., p. 39.)

Malignant or cancerous sarcoceles are represented by Cruveilhier as generally beginning in the body of the testicle; tubercular sarcoceles in the epididymis. "The former (says he) are commonly spontaneous; the latter mostly arise either from a venereal cause, a scrofulous constitution, or a contusion." (*Anat. Pathol.*, livr. ix.)

When chronic enlargement of the testicle arises from syphilis, it is sometimes called the *venereal sarcocele*. The criterion of this case, so far as the part itself is concerned, has not hitherto been well ascertained. Indeed, Sir Benjamin Brodie observes, that under whatever circumstances chronic enlargement of the testicle takes place, "the symptoms are precisely the same." He has not overlooked, however, its combination with venereal ulcers, or eruptions, as throwing light on the case. (Vol. cit., p. 222.) Dupuytren remarks, that "it would not seem difficult at first to discriminate venereal enlargements, or those produced by friction, from others which are scrofulous: I must confess, however, that, in many examples, they begin absolutely in a similar manner, and do not exhibit their true character till after a certain space of time has elapsed. The scrofulous (he says) do not generally yield to ordinary means; they are indefinitely protracted, are often accompanied by affections of the same nature, and are connected with a scrofulous constitution." (*Clin. Chir.*, t. i. p. 100.) The venereal chronic enlargement of the testicle is mostly described as coming on without pain or uneasiness, except that produced by mere distention and the weight of the tumour; but, according to Mr. Cusack, the inflammation occa-

sionally comes on rather suddenly, and in a subacute form. The disease "commences in the body of the testis; there is little alteration in the form of the organ in the first instance; but, as the enlargement advances, the tumour becomes more globular, the epididymis soon becoming involved, and lost in the general mass; the tumour has a fleshy feel, but differs much in density in different parts. It is said to be smooth and uniform on the surface, and primarily it certainly is so generally: partial adhesions in the cavity of the tunica vaginalis, however, combined with effusions into that cavity, even independent of the internal changes which may be going on, render this a very uncertain symptom: so uncertain, indeed, and so little uniform are the primary appearances, that Mr. Cusack believes the best practitioners would be unable to make a perfect diagnosis, if unacquainted with the history of the case and the attending circumstances. The termination of the disease is either resolution, or suppuration, or induration, and the formation of granular bodies, ending in total destruction of the functions of the organ. Mr. Cusack hesitates to believe, and is unable to affirm, from his own experience, that this affection of the testis is met with in the earlier stages of secondary symptoms, or during the presence of any of the forms of true papulary eruptions.

"The acute form alluded to is met with accompanying venereal hectic pains in the bones, and either a scaly eruption, or perhaps a solitary spot, apparently belonging rather to the genus Acne; but these are instances comparatively rare. The patients who suffer from this form of the disease, are such as labour under affections of the periosteum and bones, and bear the marks of having suffered from pustular and tubercular eruptions." (See *Dublin Journal of Med. Science*, vol. viii. p. 304.)

I once attended with Mr. Doughty, of University College, a horrible example of phagedenic sloughing of the penis, followed by painful enlargement and ulceration and abscess of the testes, one of which protruded in the form of a large fungus-like mass, and gradually sloughed away. The patient ultimately fell a victim to the further ravages of the disease. With respect to the diagnosis of a venereal chronic enlargement of the testicle, Dupuytren observes that we daily meet with patients who have a swelling of this organ, for which they can assign no cause. They have not received any blow or external injury; the swelling has subsided and attacked the other testicle, or has continued in one or the other to the present time. "If the tumour is oblong, or cylindrical, causes no lancinating pain when touched, the patient has had old venereal complaints; and one testicle, after having been diseased for six months, a year, or a year and a half, has resumed its healthy state, and been followed by disease of the other; there is strong reason to presume that the case is of a syphilitic nature; for a cancerous affection would not thus change its place." (See *Dupuytren*, in *Clin. Chir.*, t. i. p. 107.)

In chronic enlargement of the testicle, though a solid deposite may have taken place in its tubes, and even in its substance, or epididymis, a cure is yet practicable. This opinion, deduced by Sir Astley Cooper from a field of immense experience, and delivered by him in his lectures, receives confirmation from every quarter. "Je pense (says M. Cruveilhier) que dans l'état actuel de la science, les infiltrations de matière tuberculeuse, dans l'épididyme et même dans le corps du testicule, ne sont pas des raisons suffisantes pour l'extirpation." (*Anat. Pathol.*, livr. ix.) Sir Astley Cooper directs the patient to observe the recumbent position for a month, so as to prevent gravitation of the blood into the affected organ. Three grains of calomel and one of opium are to be given every night and morning, and the gums kept sore for at least a month. Every fourth morning a senna draught with half an ounce of sulphate of magnesia, and fifteen or twenty drops of liq. ant. tart., is to be prescribed. Leeches are to be applied twice a week, the scrotum fomented thrice a day, and a lotion of the liq. ammon. acet., with spirit of wine employed, or else equal parts of camphor mixture and vinegar. (*Sir Astley Cooper, Op. cit.*, p. 40.)

If mercury be employed, when the disease has not being going on more than two or three months, the testicle will generally be restored to a healthy state; but at a later period, it will not accomplish so much. The mercury will only stop the inflammation that exists, without having the power to restore the structure which has been already destroyed. Mercury may now relieve the pain and tenderness, and diminish the swelling; but some induration and enlargement will remain, over which mercury has no control. (*Sir B. Brodie*, in *Lond. Med. Gaz.*, vol. xiii. p. 222.) If calomel or the blue pill disagree with the stomach, mercurial ointment should be rubbed on the thigh. When the swelling is combined with a syphilitic eruption or ulcers, the bichloride of mercury joined with sarsaparilla will sometimes prove the best medicine. Dupuytren found, that small doses of the bichloride had a better effect than full ones: his custom, therefore, was to give thrice a day one pill, containing $\frac{1}{8}$ of a grain of the bichloride, $\frac{1}{2}$ a grain of extract of opium, and 2 grains of extract of guaiacum. The dose was very gradually increased to $\frac{1}{4}$ a grain of the bichloride which quantity was never exceeded. The compound decoction of sarsaparilla and sudorifics were likewise prescribed. (See *Clin. Chir.*, t. i p. 89.)

When chronic enlargement of the testicle is in the form of *hydro-sarcocele*, the fluid in the tunica vaginalis is usually absorbed under the influence of mercury, and the same remedies which cure the disease of the testicle, cure also the hydrocele. "There are cases, however, in which the hydrocele attains a large size, and in which the remedies which cure the testicle are not equal to the cure of this secondary disease. Under these circumstances, you should treat the disease of the testicle first by the exhibition of mercury; and after a mercurial course, but not till then, you may inject the hydrocele." "What would happen (asks Sir Benjamin Brodie) if you were to make an error in the diagnosis, if you were to mistake a hydrocele of this kind for a common hydrocele, and inject it before you had cured the primary disease? I did (says he) in one instance make this mistake, and I will tell you the result. A gentleman (a West Indian) many years ago consulted me about a hydrocele. There was a considerable collection of fluid, perhaps about eight ounces; I found the testicle somewhat indurated, which I thought was merely from a thickening of the tunica vaginalis; I did not, therefore, hesitate to inject the hydrocele. After the operation, no violent inflammation followed, but it did not subside as usual,

and a small abscess formed in one part of the testicle, which I opened. After this, several abscesses formed in succession in the testicle, which, all the while, went on growing larger and larger. Now I began to see the error which I had committed, and to suspect that the patient laboured under a chronic inflammation of the testicle, the hydrocele being merely a secondary affection. I put the patient under the influence of mercury, and at the moment that it acted on the gums, the abscesses ceased to form, the testicle rapidly became reduced, and, in about another month, there was an end both of the disease in the testicle and of the hydrocele; so that, in fact, every thing turned out as well as if I had adopted the proper mode of treatment in the first instance." (*Sir B. Brodie, Op.* cit., vol. xiii. p. 222.)

Scrofulous Disease of the Testicle.—I have already noticed the opinion of Baron Dupuytren, that, although it may not seem difficult at once to distinguish an enlargement of the testicle produced by syphilis, or by an external injury, from another which is scrofulous, yet, in their beginning, they sometimes absolutely resemble one another, and their true character cannot be made out till a later period. "In general (says he) scrofulous enlargements do not yield to common treatment; they continue indefinitely, are frequently accompanied by other affections of the same nature, and are connected with a strumous constitution." (See *Clin. Chir.*, t. i. p. 101.)

The following is the description given of the scrofulous testicle by Sir Benjamin Brodie. The patient experiences a slight pain in one part of the testicle, and there a little enlargement is felt, generally at one end of the epididymis. Then a slight pain is experienced at another part, and here is perceived another enlargement, which is commonly also in the epididymis. These small tumours increase in size, and gradually become more painful. Sometimes as many as three or four of these tumours are found on the surface of the testicle, generally connected with the epididymis. The skin becomes adherent to them, and one of them is converted into an abscess, which bursts through the external skin. A similar abscess forms in another, and runs the same course. These abscesses discharge very little matter, and they do not heal like a healthy abscess. When a probe is introduced into one of the sinuses thus formed, it passes down into the centre of the tubercle, or tumour in which the abscess originated. In some instances, the disease will go on, until the whole of the testicle is disorganized. Sometimes it is confined to one testicle; sometimes both are similarly involved. Occasionally it will completely destroy one of the testicles; but, more frequently, the testicle is only partially injured, and a great deal of the glandular structure remains in a natural state. In the advanced stage, the testicle sometimes becomes uniformly enlarged, and hard throughout; yet, on careful examination, the remains of the projecting tumours, which existed in the beginning, may be perceived. The disease is generally connected with other scrofulous symptoms; as enlarged glands in the neck, scrofulous disease of the spine or hip, or of some of the joints. (See *London Med. Gaz.*, vol. xiii. p. 377.)

It is remarked by Dupuytren, that the tubercular degeneration is one of the principal characters of these scrofulous enlargements. In the majority of cases, he says, the disease attacks the fibro-cellular tissue surrounding the epididymis, but that it may also occur in the substance of the testicle itself. The tubercles are developed slowly, and may continue three or four years. The mode in which they commence, their progress, their long duration, are the signs indicative of their nature. "Scrofulous swellings of the testicle are not so hard as scirrhous ones; but they are harder than those which depend upon inflammation. They are free from heat and redness; and cause a sense of weight and numbness. The subcutaneous cellular tissue is ordinarily free," or, rather, Dupuytren should have said it is so, except at the points where abscesses advance to the surface. "The shape of the tumour is commonly uneven and irregular, while, in a scirrhous enlargement, the testicle is globular, and the epididymis knobby; the spermatic cord being mostly spared, but now and then implicated. As the scrofulous disease of the testicle makes progress, certain points within the organ soften, and, when touched, seem as if they contained a soft substance. Soon after this, small bluish projections are noticed. Here the skin ulcerates, and from the openings is discharged a thin pus, and a yellowish cheese-like or pultaceous substance, evidently a product of scrofula. Fistulæ are next formed, out of which is voided a serous imperfect kind of pus. The disease may go on for years. (*Dupuytren* in *Clin. Chir.*, t. i. p. 101.)

The testicle, even in very young children, sometimes becomes enlarged and very hard, but without pain; and this indolent increase of it may remain for many weeks, months, or years; and, as the health improves, ultimately subside. More frequently the disease comes on at puberty, or between that period and the age of twenty; and, not uncommonly, it attacks both testicles. If suppuration occur, which happens even in children, but still more frequently at puberty, the matter often forms in the globus major of the epididymis, though sometimes in the globus minor. According to Sir Astley Cooper, the body of the testicle rarely suppurates; "but, after the epididymis has ulcerated, the testis becomes affected, and the scrotum assumes a livid hue; ulceration ensues, and an abscess forms, which discharges ill-formed pus, and some semen, at least after the age of puberty; and the opening is extremely difficult to heal, continuing for months, and even for years." One or both testicles at length waste, until but a small portion is left, and the seminal secretion almost entirely ceases.

In dissections of the epididymis and testis affected with scrofulous disease, Sir Astley Cooper has found a yellow spot surrounded with a zone of inflammation in the globus major, or sometimes, though less frequently in the globus minor. When the spot ulcerates in its centre, the matter which is voided is not pure pus, but composed of fibrine and serum, and having a slight yellow tinge. "In the testes there are several similar yellow spots, accompanied by the same kind of inflammatory zone; and several yellow streaks are also found amidst the tubuli. Scrofulous abscesses in the testes are sometimes accompanied by a granular swelling, like that which exists in the simple chronic disease." (*Sir Astley Cooper, Op.* cit. p. 97—99.)

Mercury, which proves so efficient in the ordinary chronic enlargement of the testicle, does harm in the scrofulous disease of it. No specific remedy for scrofula is known; but the patient should have the benefit of pure air, and especially of that of the coast. The diet should be nutritious, and ale, or porter, or wine and water be the drink at dinner. Sir Astley Cooper speaks also in favor of tepid sea-bathing. The medicines which he commends, are hydr. cum creta with rhubarb; powder of columba with rhubarb and soda twice a day; vinum ferri; tinct. ferri muriatis; tinct. ferri ammon.; or pills composed of rhubarb and carbonate of iron; quinine with infus. rosæ comp.; liquor potassæ; the bichloride of mercury in minute doses, joined with the compound decoction of sarsaparilla, or with tincture of bark, or of rhubarb.

Sir Benjamin Brodie enjoins a regulated diet, residence at the sea-side, and the exhibition of steel medicines, or quinine, where they seem to be required, as they generally are. But he has seen more benefit derived from the liquor potassæ than any other medicine. It is to be combined with tincture of gentian, and taken in the dose of half a drachm three times a day, blended with a wine-glass of table-beer. The acetate of potash, which may be produced by this mixture, Sir Benjamin conceives has also a good effect by acting as a diuretic. (See *Lond. Med. Gaz.*, vol. xiii. p. 378.) Preparations of iodine are well known to be serviceable in this disease; and the tincture, or what is better, the iodureted solution of the hydriodate of potash, may be exhibited with caution.

In the indolent stage, previously to suppuration, the ointment of iodine, or linimentum hydrargyri, may be rubbed on the part, the emplastrum hydrargyri applied, or lotions of the liquor ammon. acet. and spir. vin. used. If the disease suppurate and ulcerate, a solution of one grain of sulphate of copper in an ounce of distilled water may be employed as a lotion, and also as an injection for the sinus, or liq. calcis ʒiv and hydrar. chloridi ʒj: nitrate of silver lotions are also eligible.

The *cystic*, or, as Sir Astley Cooper names it, the *hydatid*, or *encysted disease of the testicle*, is comparatively rare, and described by him as a specific, yet entirely a local disease, as he has seen it in persons who enjoyed excellent health, and in whom no relapse occurred after the part had been removed. It is chiefly met with in persons between the ages of 18 and 35; and is alleged to begin with enlargement of the epididymis. It is not painful until the part is large, and the unyielding tunica albuginea makes pressure on it. When handled, there is no feeling of tenderness manifested, unless the pressure be considerable. The frequently healthy look of the patient is apt to create suspicion of hydrocele. The spermatic veins and those of the scrotum are distended. The natural form of the testis is preserved, being rounded in front, and flattened at the sides, and not so pyriform as in hydrocele. When the swelling is handled, it communicates an impression that it contains a fluid, for it easily yields to pressure; yet there is no true fluctuation, for the tumour does not rise at a distance, as it sinks under the pressure of the finger; but it yields only at the spot compressed. If strongly compressed, a sickening pain in the groin and loins is produced. The weight of the testicle is obviously increased, and after a time, this causes pain in the lumbar region, and its bulk is a great inconvenience. The complaint seems to Sir Astley Cooper to be so local, that were it not for its weight and size, it would scarcely call for removal; for the spermatic cord does not become affected, nor are the absorbent glands in the loins or groin irritated by it.

In the dissection of this disease, the tunica vaginalis is found thickened, and partially adherent; and the tunica albuginea, both of the epididymis and testicle, is much denser than natural. The testicle consists partly of a solid structure, and partly of cysts, varying in size from that of the head of a large pin, to that of a small marble. The small cysts contain a transparent, yellow, serous fluid; the larger, a mucous secretion. The cysts which contain serum are highly vascular. Sir Astley Cooper suspects the cysts to be enlargements of the seminiferous tubes from obstruction; but on this point he is doubtful. He admits that they are certainly not of the nature of animal hydatids. The cysts in the epididymis do not become so large as in the testicle. There are some fine specimens of this disease in the various pathological museums of London: the best which I have seen are in those of the late Mr. Abernethy, and of Mr. Liston.

The marks of distinction between this cystic disease and hydrocele, are that the former is characterized rather by a yielding than a fluctuation; by a heavier swelling; by the swelling being less pyriform than a hydrocele; by the entire absence of transparency; by the sickening pain caused by strong compression of the tumour; and by the dilated state of the veins of the spermatic cord and scrotum.

The removal of the part by operation is the only means of relief; for the change of structure, attending the disease, manifestly amounts to a disorganization of the part not admitting of benefit from any internal or external remedies. "A system of depletion and abstinence for a week (observes Sir Astley Cooper) will make the patient bear the operation well; and it is one which, for this disease, I never knew unsuccessful." (*Op. cit.*, p. 86.) The following modification of this statement, however, deserves well to be remembered. "The fungoid (medullary) and encysted disease may be combined in the same testis, and then the case may prove fatal; but this will be ascertained by the dissection of the removed part, which will lead to a favourable prognosis in the encysted disease, and to a very decidedly unfavourable opinion in the other. Cruveilhier (livr. v. pl. 1, figs. 1 and 2) has given a most correct view and description of one form of the latter unfortunate combination, which he terms *cancer alvéolaire* avec matière perlée, on account of some of the cysts containing a pearl-coloured substance, but others a serous fluid, and others again a pultaceous matter. In this case, castration was performed, and the wound quickly healed; but six months afterwards, medullary tumours formed in the substance of the bodies of the seventh cervical and fifth dorsal vertebræ, and by compressing the medulla, occasioned paralysis, first of the upper, and then of the lower extremities, abdominal parietes, &c., terminating in death.

Medullary Cancer of the Testicle. Fungus Hæmatodes. Pulpy Testicle. Medullary Sarcoma. Fungoid Disease of the Testicle.—Organic diseases of the testicle are found to be less common at the present time than they were believed

to be formerly, when chronic enlargements of that organ were always confounded with them. The discrimination of one class of cases from the other, the result of which has been to render the extirpation of this part a comparatively rare operation, appears to me to be one of the greatest improvements in modern surgery. Medullary cancer of the testicle, a disease bearing such a variety of names, usually begins with an enlargement of the body of this organ, which is at first attended with considerable hardness, and the swelling often increases rather quickly, "so that in three or four months, the whole of the testicle will become diseased. It then affects the epididymis from one extremity to the other. Whilst the complaint is confined to the testis, the swelling is globular; but when the epididymis is also diseased, it becomes pyriform, and has so much the form of hydrocele as at first sight to be easily mistaken for it. This deception is rendered the more easy, as a small quantity of water is often effused, so that the complaint has been called *hydro-sarcocele*. When carefully examined by manipulation, the solid swelling is felt through the water, and the sides are found flatter than its forepart, which is the form of the testicle in its natural state. The surface of the testicle is frequently uneven; but this symptom is not a concomitant of this disease in its early stages. At first, the complaint is not painful; but it is soon followed by occasional darting pains in the part, and in the course of the spermatic cord to the groin and loins, and, if it be much handled, it leaves a tenderness and increased pain in the part. Its growth is very uncertain; it sometimes increases quickly, and acquires great size; at others, eight or ten months elapse, before the swelling is considerable. It also does not grow steadily and equally; but becomes very painful for two or three days, and during that time rapidly increases; and then it is stationary for two or three weeks." At first, the colour of the scrotum is not changed, and the spermatic cord is not swollen, excepting that the veins are slightly enlarged. In the second stage, it is covered with varicose veins, and the testis, instead of being hard, yields to pressure, and both the elastic feel and the pyriform shape of the tumour raise a suspicion of its being a hydrocele. The spermatic cord becomes enlarged up to the abdominal ring, and the spermatic veins are fuller than natural. The patient's countenance is sallow; sometimes he is constipated, sometimes he has profuse diarrhœa; his appetite fails; his rest is interrupted by pain; and he falls into a state of great emaciation.

In the third stage, the testicle becomes adherent to the scrotum, and the skin can no longer be readily moved over the tumour. In the groin on the diseased side, one or more absorbent glands enlarge from irritation; and after many glands there have become affected, those in the opposite groin also enlarge. The surface of the testicle now feels knobby and unequal; and sometimes the spermatic cord, besides being enlarged, indurated, and varicose, becomes adherent to the pubes, and to this point the testicle is firmly bound. At length, at a particular point of the scrotum, a purple blush appears, under which a fluctuation seems so distinct, that the surgeon is often induced to make a puncture; but merely blood is discharged. Although the wound thus made heals, yet soon afterwards ulceration ensues, and a fungus projects, bleeds, and discharges a profuse quantity of thin serous fluid, which has a peculiar faint odour. In two or three weeks, the ulcer spreads to the breadth of the palm, sloughs frequently, is extremely offensive, occasionally very painful, but not tender to the touch; and if the testicle be compressed, a brain-like substance issues from the fungus At last, the patient sinks from hemorrhage, serous discharge, and continued irritation. (*Sir Astley Cooper, Op.* cit., p. 118—120.) I have never seen the disease in that advanced condition where ulceration has occurred, and a mass of fungoid substance has protruded. I believe, with Sir Benjamin Brodie, that the opportunities of doing so are rare, because the testicle is generally amputated, or the patient dies, long before the disease gets to this point. It is certain also that the tumour may grow to an enormous size, without any ulceration of the scrotum, or protrusion of the medullary substance taking place. In one or two examples, in which I was led by the elastic feel of the tumour to make a puncture, the wound healed up, and never gave any further trouble. This agrees with the observations of Sir Benjamin Brodie; but I should remark, that the punctures in my cases were made in an earlier stage than that referred to by Sir Astley Cooper, the purplish blush not presenting itself at the point where the lancet was introduced.

The writings of Professor Carswell convey most accurate views of the chief characters of medullary cancer, or *cephaloma*, as he calls it. In his able work, entitled "*Illustrations of the Elementary Forms of Disease*," this subject is considered in a manner which cannot fail to be highly interesting to every inquirer into the pathology of surgery. But as I have noticed his statements in other articles, (See CANCER, and FUNGUS HÆMATODES,) it is unnecessary here to repeat them. With respect both to scirrhous and medullary cancer, sometimes the new deposite takes place in the molecular structure of the part affected, after the manner of nutrition; while, in other instances, it is thrown out on a free surface, rather in the manner of secretion; or, as Sir Benjamin Brodie has explained, there are some cases, in which a particular organ loses its natural structure, and becomes converted into a diseased one; and there are other cases, in which the morbid growth is altogether a new formation—a tumour, growing in a particular part of the body, which remains entire, and retains its natural organization. Now, with respect to medullary cancer, or fungus hæmatodes, it appears that, in some cases, the glandular structure of the testicle is actually converted into this diseased structure; but there are others in which the new deposite collects in a distinct mass, and the glandular structure of the testicle is, for a time at least, entire. Sometimes the new deposite accumulates in a mass in the centre of the testicle, and the glandular structure is expanded, as a thin layer, upon its outside. Mr. Wardrop relates a case, in which the glandular structure was natural, the tumour having grown from the surface of the tubuli testis, immediately beneath the tunica albuginea. Sir Benjamin Brodie refers to a specimen, in which the glandular structure continued sound, while there was a large medullary tumour completely occupying the cavity of the tunica vaginalis. "However distinct the testicle may have been in the first instance, it becomes at last confounded with the disease; and there is then a tumour of an oval shape, and in this respect different from hydro-

cele. It is also heavier than a hydrocele; opaque instead of being transparent; harder at some parts than others; and without the smooth regular surface of hydrocele. The softness and elasticity of the tumour, however, have often caused it to be mistaken for hydrocele, and punctured." (See *Wardrop on Fungus Hæmatodes; Earle*, in *Med. Chir. Trans.*, vol. iii. p. 60.)

Notwithstanding the deceitful feel of fluctuation, dependant on the elasticity of the swelling, a well-informed surgeon will generally arrive at a correct diagnosis; but if there be doubt, Sir Benjamin Brodie sanctions puncturing the tumour with a very small trocar. "If it be a hydrocele, the serum escapes, and the tumour disappears; but if it be fungus hæmatodes, there comes out a little blood, and that is all. No harm is done by the puncture." The bleeding soon stops, and the wound heals. (*Sir B. Brodie*, in *Lond. Med. Gaz.*, vol. xiii. p. 407.)

I have already mentioned the occasional combination of the disease with hydrocele, constituting one of the cases, sometimes termed *hydrosarcocele*. More frequently, the cavity of the tunica vaginalis is obliterated by adhesion; or there may be partial adhesions, and partial hydrocele.

In the dissection of a testicle, which was the seat of this disease in the early or first stage, Sir Astley Cooper found, that the excessive hardness of the part did not arise from the solid nature of the substance deposited in it, but from the excessive distention of the tunica albuginea, and from its not readily yielding to the pressure from within. "The substance which was effused was fibrous, of a yellowish white colour tinged with blood, partially vascular, and, when macerated, it became flocculent, and had the appearance of matted wool. The seminiferous tubes ceased to be observable at that part of the testis; but, in other parts, they remained entire. In the dissection of the testis in the second stage of the disorder, it is found filled with a similar soft and white fibrous matter, which occupies the testis and epididymis, and the parts of which readily yield to pressure. And there is intermixed with the soft effusion a yellow fibrine." When macerated in this state, the soft fibrine is removed, and the tendinous septa of the testis in which it has been enclosed are left, representing a kind of cellular structure. In the third stage, when the testis is excessively enlarged, the tunica vaginalis contains a good deal of fluid; the tunica albuginea has given way, and a portion of the disease projects through it. The interior of the testis may likewise contain cysts of serum, as well as coagulated blood, and the white soft fibrous matter already noticed, from which, when compressed, a substance issues like cream tinged with blood, and sometimes compared to putrid brain; the epididymis is enlarged, and where serum has not been effused, the tunica vaginalis is adherent to the testicle. (*Sir Astley Cooper, Op.* cit., p. 121.) The same distinguished surgeon notices the frequent enlargement and induration of the spermatic cord, and its exemption from the disease in certain other cases which have even had a fatal termination. On this point Sir Benjamin Brodie remarks, that "when the disease first exists, the spermatic cord is in a natural state, and, in many cases, it never seems to be much enlarged; but, in other instances, the disease extends to the spermatic cord, and this to a very great extent. Seeing this, you will not wonder that disease should take place in the loins, where some parts of the spermatic cord originate. The disease, however, will show itself in the loins, although the spermatic cord be healthy. This I have seen many times in examining bodies after death." (See *Lond. Med. Gaz.*, vol. xiii. p. 408.) The same fact was exemplified in a case in University College Hospital, where, at the earnest entreaty of the patient, a man about 30, I removed a testicle affected with this disease; and, though he afterwards fell a victim to an enormous tumour of the same nature in one of the lumbar glands, the portion of the spermatic cord removed, and also that left within the inguinal canal, were free from disease. In another case where I operated, the part of the cord taken away contained little bodies like millet seeds in size; and, notwithstanding this unfavourable circumstance, the patient recovered, and was apparently in health, at least two or three years after the operation; and, so far as I know, may even continue well to the present day, which is six or seven years from the time when the testicle was removed.

Frequently a quantity of serum is found in the abdomen, and behind the duodenum, "a large tumour, to which that intestine adheres on the forepart, and the aorta and vena cava are placed behind it. It is in different subjects of a size from that of the clinched hand to that of the head of a child. When cut into, it contains a soft, but still a solid fibrine, with which is intermixed a fluid like cream, slightly tinged with blood. In some persons, the tumour in the abdomen begins from the lower part of the loins, and extends to the diaphragm, involving the kidney; and, when it is attempted to be dissected, a large quantity of a thick cream-like matter bursts from it at different parts. The aorta and vena cava are diseased, and fungous tubercles and effusions are produced in their coats, and fungous (medullary) effusion into the interior of the aorta." In many of these cases the mesenteric glands are similarly diseased. Frequently the liver is loaded with tubercles of the same nature; and in the museum at St. Thomas's Hospital is a preparation in which the thoracic duct is obliterated by this disease. (See *Sir Astley Cooper, Op.* cit., p. 121—124.) In an example dissected by Mr. Lawrence, the swelling of the testicle consisted of cellular septa, filled with pulpy matter; numerous tubercles of the disease were found in the omentum, and in various parts of the pelvis, intermixed with recently effused coagula. A mass of soft matter, equal in size to a man's head, lay on the spine, behind the aorta and vena cava, which last vessel was closed for some extent. The spermatic vessels could not be found. (See *Med. Chir. Trans.*, vol. viii. art. 13.)

The young man from whom I removed a testicle in University College Hospital, on account of this disease, was afterwards destroyed by the effects of an enormous swelling of one of the lumbar glands, which was as large as a man's head. It not only compressed the duodenum and vena cava, but a portion of it had made its way into the pelvis of the kidney. This patient suffered excessive pain for several weeks before he died, and was reduced to an extreme state of emaciation, the stomach having been able to retain scarcely any thing in it. The swelling of the lumbar gland could be plainly felt through the abdominal parietes. It is observed by Sir

B. Brodie, that "in many cases the tumour in the loins gives the patient no pain, and but little inconvenience; while, at other times, it is attended with the most extraordinary suffering. A gentleman (he adds) with whom I was acquainted many years ago, had this disease in the testicle; Mr. Cline was consulted, and he recommended the amputation of the testicle, and performed the operation. A year afterwards, the patient became weak in his lower limbs, and at last they became completely paralytic. He died; and, on examining the body after death, there was found a large tumour in the loins, which had affected the vertebræ, so as at last to press on the medulla spinalis; thus accounting for the paraplegia." (*Sir B. Brodie*, in *Lond. Med. Gaz.*, vol. xiii. p. 408.)

Dr. Macfarlane has recorded an instance, in which the patient died of peritonitis: the particulars confirm several circumstances in the preceding account. "The abdominal cavity contained a pound of sero-purulent fluid. The peritoneal coat of the stomach and intestines was extensively inflamed, and covered with patches of lymph. The liver was enlarged, softened, and had a motley appearance. There was *a tumour nearly as large as a child's head, situated under the transverse arch* of *the colon*, and covered by the small intestines. *It lay close upon the spine, and was firmly attached to the aorta, vena cava, and left kidney.* A section of the mass showed it to be composed of a *soft brownish substance, which resembled brain mixed with blood*, and from the more solid parts a fluid, like pus, was squeezed out. The inferior part of the testicle presented the same appearance and structure as the abdominal tumour, but the upper half was firm, grayish, and slightly fibrous. The epididymis was enlarged; the tunica albuginea thickened, &c. *The spermatic cord was sound.* (See *Macfarlane's Hospital Reports.*)

In Sir Astley Cooper's valuable work on the *Structure and Diseases of the Testis*, is an interesting plate (viii.) representing the appearances presented in an instance where the castration had been performed, but a relapse occurred. There the end of the spermatic cord is seen forming a considerable tumour; a large tumour may be noticed in the groin; and a very considerable mass between the left kidney, ureter, and sigmoid flexure of the colon.

The only chance of a cure (and this a very poor one) must be derived from the early performance of castration, before the disease has extended to the lumbar or inguinal glands, or far up the spermatic cord. Indeed, very little hope should be placed in the removal of the testicle; for fungus hæmatodes appears to be rather a constitutional, than a local disease. Nearly every case on record has terminated fatally, and, upon dissection, either the liver, the lungs, the brain, the lumbar or mesentric glands, or other internal parts, have been found affected with the same disease. In one case dissected by Mr. Lawrence, tubercles of a similar structure to the disease in the axilla, were found in the lungs, heart, and, in short, in nearly all the thoracic and abdominal viscera, though the contents of the scull were free from disease. (See *Cases recorded by Wardrop, Earle, Lawrence, and Langstaff*, in *Med. Chir. Trans.*, vol. iii. and viii.)

Mr. Travers states, that he has never known an instance of the non-recurrence of the disease after castration. (See *Med. Chir. Trans.*, vol. xvii. p. 335.) And Sir Astley Cooper observes, that of all the operations of surgery, there is scarcely any which is so generally unsuccessful as that of castration for this disease; and there is no hope of the patient's life being saved, unless the operation be performed as soon as the nature of the complaint is ascertained. (*Op.* cit., p. 131.)

Dr. Baillie observes, that the testicle is often found converted into a hard mass of a brownish colour, and generally intersected with membranes. Sometimes there are cells in the tumour, which are filled with a sanious fluid. (*Morbid Anatomy, &c.*, pp. 352, 353, ed. 2.) This is what is usually termed the *scirrhous testicle*, which is attended with great hardness, severe pains dart ing along the spermatic cord to the loins, and an unequal knotty feel. In general, the health becomes impaired. To use Mr. Pott's words, sometimes the fury of the disease brooks no restraint; but making its way through all the membranes which envelope the testicle, it either produces a large, foul, stinking, phagedenic ulcer, with hard edges, or it thrusts forth a painful gleeting fungus, subject to frequent hemorrhage. (*Pott's Chir. Works*, vol. ii. p. 390, edit. 1808.)

Pott's description probably comprises several forms of disease, and confounds them together, as for instance fungus hæmatodes, scirrhous cancer, and even chronic enlargement with protrusion of fungous granulations and a portion of the substance of the testicle. Now, it deserves attention, that the kind of disease formerly recognised by surgeons as *scirrhus* and *cancer of the testicle*, and specified by Dr. Baillie, is found at the present day to be at all events not a common occurrence. Mr. Travers declares himself "incredulous as to the fact of the scirrhous cancer affecting the testis." (*Med. Chir. Trans.*, vol. xvii. p. 327.) Sir Astley Cooper remarks:—"I much doubt the existence of this disease in the same form and appearance as it assumes in the breast, viz., an excessively hard swelling, intersected by a network of strong fibres, or bands. I have seen a few instances of a very solid enlargement of the testis, accompanied with great weight, attended with severe occasional pain, beginning in the body of the testis, never becoming soft, like fungus, or producing a fungoid and very vascular bleeding surface, but feeling tuberculated, irregular, and excessively hard, but never becoming so large as the fungoid disease; the pain extending to the loins; the spermatic cord enlarged, hardened, and tuberculated; a smaller tumour than that of the fungoid disease, forming in the abdomen. Some water is secreted into the tunica vaginalis. At length, a dropsical effusion into the cellular membrane of the leg and thigh of the diseased side is produced, and then the other leg becomes similarly affected." On dissection, instead of the seminiferous tubes, a hard white substance is found in tubercles of little vascularity, and sometimes interspersed with small portions of cartilage, or bone. The epididymis contains the same kind of deposite; and the spermatic cord, which is enlarged, has small white tubercles in it. The tumour in the abdomen is also of a white solid texture, very unlike that of the fungoid disease. This disease has less tendency than the fungoid or medullary to involve different parts of the body together, and is slower in advancing to its fatal termination. Hence the disease affords more time for the trial of calomel and opium, with

leeches, evaporating lotions, and the recumbent posture, but, as Sir Astley Cooper rightly adds, great care must be taken not to defer the operation of castration so long, as to let the disease implicate the spermatic cord, or a tumour to be formed in the abdomen.—(*On the Structure, &c., of the Testis*, p. 152—154.)

Neuralgia of the Testicle. Irritable Testicle.—By these expressions is signified a highly sensitive and exceedingly painful affection of the part, generally unaccompanied by any swelling, or other obvious change in it. The suffering is frequently of the most excruciating kind, and of long duration, though subject to occasional remissions. "A patient frequently complains of pain in the testicle when there is no disease in it. There is a state of the nerves of the part, which makes him feel pain in it, although there is no inflammation, nor any other actual disease; and this is all that we mean when we talk of a neuralgic affection in this or any other part of the body. You will find an example of it in persons in whom a large calculus passes from the kidney to the bladder. As soon as the calculus has passed a little way down the ureter, the patient complains of pain in the testicle, which is at the same time frequently drawn up by the spasmodic action of the cremaster muscle into the groin. When you examine it, you find it of its natural size, natural shape—at first not even tender, although excessively painful; in short, there is a painful affection of the testicle, depending not on any disease of the organ itself, but on the influence which the calculus, in passing down the ureter, exercises on the spermatic plexus of nerves. Disease in the kidney will sometimes produce pain in the testicle, although there is no reason to believe that a calculus, or other substance, has escaped from the kidney into the ureter." (*Sir Benjamin Brodie, Lond. Med. Gaz.*, vol. xiii. p. 620.) From the observations delivered under the head of *Neuralgia*, the reader will perceive, that neuralgic affections may depend upon a great variety of circumstances, and especially on derangement of the general health. In the dissection of a testicle that has been the seat of neuralgia, no change of structure can be found. In one instance which I attended, there was occasionally a little enlargement of the organ, though for the most part it remained free from all swelling or other manifest alteration. If the complaint be connected with functional disturbance of the liver or stomach, the chance of relief must depend upon the possibility of curing this primary affection. In many cases, which appear to be entirely nervous, or not associated with any other perceptible fault in the system, large doses of the sulphate of quinine, or of the carbonate of iron, may be prescribed; or, if the disease assume an intermittent type, and come on periodically, the liquor arsenicalis. In some cases, the muriate of morphia, opium, or hyosciamus, joined with calomel, will answer best; and, if the liver be disordered, and the secretion of the skin checked, calomel, opium, and James's powder, should be tried. As local applications, leeches, ice-cold lotions, ice itself, or a plaster, one third of which consists of extract of belladonna, and two thirds of soap cerate, or the veratria ointment, deserve to be particularly specified. For additional remarks relating to neuralgic affections, see NEURALGIA.

Atrophy, or wasting of the Testicle.—Sometimes this organ is either partially or completely absorbed. This may happen from a blow or other injury which causes violent inflammation of the part, and disorganization of it. Obliteration of the vas deferens has been observed to be attended with a dwindling away of the testicle; a circumstance which would be expected from the recollection of the functions of the organ being necessarily destroyed by such obliteration. Varicocele sometimes leads to atrophy of the testis; and sometimes the obliteration of the principal spermatic veins with a ligature or forceps, adopted for the cure of varicocele, has been followed by this change in the testicle. Acute inflammation of the testicle from gonorrhœa; chronic enlargement of it from other causes; and especially scrofulous disease of the organ, may, in the end, lead to atrophy of it: in the first case, possibly, in consequence of the vas deferens becoming sometimes permanently obstructed; but in the other two examples, no doubt, from disorganization of the testicle itself. The pressure of a large hernial swelling I have often known occasion atrophy of the testicle; and the strong compression of the spermatic cord by a truss would appear to be capable of producing the same consequence. Atrophy of the testicle was remarked by Baron Larrey to occur with remarkable frequency after the deep sabre-cuts of the back of the neck, received by the French soldiers in Egypt, in their contests with the Turks. Onanism and excessive venery are believed to lead in some instances to atrophy of the testicle.

The *induration and swelling* of the testicles resulting from effusion of urine in the scrotum, and often accompanying fistulæ in perinæo, will subside after the disease of the urethra has been cured. (See *J. Cloquet, Pathologie Chir.*, p. 44.) Every surgeon of experience must have witnessed this fact.

The late Mr. Ramsden thought, that some sarcoceles might be relieved by removing with bougies a supposed morbid irritability of the urethra, with which his theories led him to connect the origin of the complaint. (See *Pract. Obs. on Sclerocele, &c.*) No doubt many chronic enlargements of the testicle have subsided during this treatment, especially when aided by calomel and other means; but a doubt may be entertained whether the bougie had any essential share in producing the benefit obtained. The practice, at all events, is not at present much adopted, though, on the first suggestion of it, many trials of it were made.—C.]

[Dr. Pancoast, of Philadelphia, has had occasion, very frequently, to remove schirrous testes, and in all the cases attended with encephaloid softening, the disease has returned in the abdominal viscera or lumbar glands; nor does the freedom of the vas deferens from the disease, afford any guarantee against its return, according to his experience.—REESE.]

[TETANUS. Dr. Alex. E. Hosack, of New York, has succeeded in curing two cases of traumatic tetanus by the free use of wine and brandy, and in one instance so completely was the patient saturated with these potations, that an attack of delirium tremens supervened, which was well characterized, and to this Dr. Hosack attributes the cure. In both cases the patients laboured under the most violent symptoms of the disease, and opisthotonos was present. Dr. Delafield was also in attendance and witnessed the favourable result.—REESE.]

[TIBIA. Dr. J. C. Warren has excised the

tibia for necrosis in four cases, in three of which he was successful. Dr. M'Clellan has repeatedly removed the tibia, humerus, and femur, under like circumstances.—REESE.]

[TONGUE. Dr. Thos. Harris, of Philadelphia, has twice extirpated the tongue for hypertrophy of that member, and the patients have recovered. Dr. Mutter, of the same city, has lately repeated the same operation with entire success. Dr. Mussey reports a similar operation in the Amer. Jour., for 1838. In the same journal, for 1836, Dr. Donnellan, of Louisiana, reports a case, in which he removed a greater portion of the tongue by ligature.—REESE.]

[TONSILS. Dr. Alex. E. Hosack, of New York, was the first surgeon in America who removed the tonsils by excision, instead of the ligature, which had long been employed for the purpose. He published a paper on the subject in the Amer. Jour., for 1827, which first called the attention of the profession to the use of the knife, which, under various modifications of instruments, is now universally used. Dr. Physick practised for many years the removal of the tonsils by the use of a double canula and iron wire, but the inconvenience often occasioned, by the troublesome sequelæ of this method, induced him to adopt excision as early as 1827. At first he used the scissors, but soon constructed an instrument for removing the uvula or tonsils, which is described in the Amer. Journal, for 1827. Dr. Hosack and Dr. Stevens, of New York, and Dr. Fahnestock, of Bordentown, have each devised instruments for the purpose, and Dr. Gibson, of Philadelphia, describes one of his own in the late edition of his Institutes and Practice of Surgery. Different American surgeons and instrument-makers have variously modified these instruments, and Mr. Tieman, of New York, belonging to the latter useful profession, has devised one which is very generally preferred to all others, as it serves to fulfil all the indications, and obviate all the dangers occasionally incident to the operation.

In the Philadelphia Med. Examiner, for 1839, Dr. John Mason Warren has a paper on enlargement of the tonsils, attended by certain deformities of the chest, which he has observed, particularly in children. His father, Dr. John C. Warren, has removed the tonsils, by excision, 200 times. To guard against the hemorrhage which has occurred when the bistoury has been used, he employs an instrument of his own, having an oval aperture to receive the tonsil, and a concave cutting blade is attached, which excises it readily, the pillars of the palate being forced back and protected. Nine-tenths of these operations were rendered necessary by the difficulty of breathing, either occasioned by the enlarged tonsils, or co-existing and relieved by their removal. The rest were for deafness or imperfect articulation.

Dr. Warren has closely investigated all his cases which were accessible, since the publication of Dr. Parish's paper on the Change of Voice, which he ascribes to the excision of the tonsils, never having before observed it, nor has he since found any confirmatory evidence. He thinks that there must have been a wound in the pillars of the palate, in such examples as those of Dr. Parish, in which this change of voice occurred, and he ascribes it to the imperfection of the instrument which must have been employed in their excision.—REESE.]

[TRACHEOTOMY. Since the note inserted under the head of bronchotomy was prepared, I have had occasion to perform this operation upon a child nine years old, who was near suffocation from the presence of a tamarind seed in the trachea. The œdema, and other diagnostic symptoms, fully satisfied me of the presence of the foreign body; but on opening the trachea, its presence could not be detected. The opening was enlarged, and suffered to remain open half an hour, but nothing could be seen or felt of the seed, although the alarming symptoms subsided, and the most satisfactory relief was obtained. I felt assured that the foreign body was lodged below the incision, perhaps at or near the bronchial bifurcation, and did not despair of yet accomplishing its removal. An obstinate cough continued, with irritative fever, for several days, when a small portion of the seed came up by expectoration. But it was not until three weeks had elapsed that the main body of the tamarind seed came up during a paroxysm of coughing, and the little patient is now convalescent.

In this case, although the operation did not immediately accomplish the object to which it was directed, yet there can be no doubt that it preserved the life of the patient; for at the time of its performance, the child could have survived but a short time. The decided improvement in the respiration which supervened upon the operation, and the absence of every bad symptom said to be apprehended after bronchotomy, satisfied us fully of the safety and utility of opening the trachea in dangerous cases of trachitis from any cause. For although the opening was made of a crucial form, first by dividing the cartilage between the rings, and then by a longitudinal incision half an inch in length, yet, after leaving it open half an hour, it was closed by adhesive plaster, and in less than a week had entirely united; the air only escaping at the opening, at intervals, during the first few hours.

Dr. Trowbridge, of Watertown, has performed this operation nine times successfully, for the removal of foreign bodies and for croup. In the Med. Trans. of the State of New York, for 1819, he describes new instruments for this operation; and, indeed, for all operations upon the throat, including a *distender* for keeping open the parts divided, and which he regards preferable to tubes.

The late Dr. Physick recommended this operation in the treatment of hydrophobia, as long ago as 1802, in a paper published in the New York Med. Repos. for that year. He was led to make this suggestion from observing, in a fatal case, that the spasmodic contraction of the muscles of the glottis kept the patient suffering for days with all the horrors of impending suffocation, respiration being at times wholly suspended. To this morbid condition he attributed the dread of water, supposed to be characteristic of hydrophobia. Whether he ever had the opportunity afterward of trying the efficacy of tracheotomy in such a case, I am not informed.

Dr. Mott has repeatedly performed this operation for the removal of extraneous substances from the larynx, or trachea, with uniform success, except when the foreign body has been lodged in one of the bronchiæ; and in one example which proved fatal, after this operation had been performed, a piece of the kernel of a walnut was found impacted in each bronchia.

A few months since, he removed a large black shawl pin, two inches in length, and having a

head nearly the size of a small marble, from the trachea of an infant eleven months old. It had been there forty-eight hours, and though its length presented great difficulty in its removal after getting hold of it, yet he ultimately succeeded, and the infant recovered.

As this operation is generally required in children, it is always difficult, especially as the emergency often demands its performance by candle-light. One thing is important to be remembered, viz., that for the success of tracheotomy, great caution is indispensable, that it should be performed very slowly, and especially that the opening must not be made into the trachea until every drop of blood has ceased to flow. Without this precaution the child may perish from strangulation, even though only a very small quantity of blood may have entered the trachea. This catastrophe has resulted from this operation, and in one recent case it occurred in this city, and in the hands of a reputable surgeon.—REESE.]

[TREPHINING. Dr. J. C. Warren, of Boston, has twice cured epilepsy by trephining the scull. In one case of paralysis, for which he performed the same operation, he was unsuccessful. In the Boston Med. and Surg. Journal, he has published a case of neuralgia of the inferior maxillary nerve, for which he applied the trephine to the ramus of the lower jaw, and cured the disease by this operation.—REESE.]

[TUMOURS. Under this head I am permitted to add a highly interesting case of tumour in the neck, in which the operation for its removal was performed by Professor Alden March, of Albany, N. Y. And although this operation was unsuccessful, yet the cause of its failure was apparent, and ought to be known to the profession, that it may be avoided in future surgical wounds, in which the neck is to be involved. This operation was performed in August last, and the patient died on the table, from the introduction of the air into the cavity of the heart, through the external jugular.

The tumour was as large as a pint bowl, occupying the left side of the neck, somewhat egg-shaped, having its largest extremity turned upwards, encroaching on the lobe of the ear, so as to project it considerably, and inferiorly extending nearly to the clavicle.

The following is the report furnished of the operation from notes taken at the time:—

The first incision was commenced under the lobe of the ear, and, pursuing a curvilinear direction, terminated at the sternal extremity of the clavicle. A second incision was commenced in the line, and within an inch of the top of the former, and extending downwards in an opposite direction, terminating within an inch and a half of the sternum. A third was commenced upon the base of the jaw, at an inch distant from the chin, and carried backwards and upwards, so as to form an angle with the top of the first, and terminating at the posterior and superior portion of the mastoid process of the temporal bone.

The anterior flap was raised and turned over the larynx, which exposed the cervical fascia, inasmuch as the muscular fibres of the platysma-myoides were obliterated. The fascia was divided over the anterior margin of the sterno-hyoideus muscle to the extent of nearly two inches, which exposed the muscular fibres of the omo-hyoideus. In the angle formed by these and the lower and anterior portion of the mastoid muscle, the carotid artery was exposed and secured with two ligatures.

The next step of the operation was to separate the upper part of the tumour from the base of the jaw, the submaxillary and parotid glands, both of which were found to be in a perfectly natural and healthy state. At the point where the labial or fascial artery passes through the submaxillary gland, it was divided, or a large branch of it. It bled quite freely, although the common carotid had just been secured. This branch must have derived its blood from the internal carotid of the opposite side, by the way of the circle of Willis, by the vertebral, or by the superior thyroidal of the opposite side, or perhaps from these several sources. This and the carotid were the only arteries which were secured by ligatures.

The next step in the operation was to dissect the posterior flap from the surface of the tumour, when it was found that the muscular fibres of the sterno-cleido-mastoideus were completely obliterated over the centre of the tumour, or reduced to a mere tendinous fascia. The dissection was then directed to detaching the tumour from above and below, of course avoiding the chief branches of the carotid, as well as the trunk, the pneumogastric nerve, and the great internal jugular. At this period of the dissection the tumour became loose, and an immediate and successful completion of the operation was confidently anticipated. But while cautiously dissecting at the lower part of the attachments of the tumour, the external jugular vein was divided very near the point at which it unites with the internal jugular. At this moment *a phenomenon occurred* which was most alarming. It was *the noise of a strange rushing of air*, as though the trachea or cavity of the thorax had been cut into, and seemed to threaten the instant dissolution of the patient; a noise resembling the sudden pouring a liquid from a junk-bottle. The patient was instantly seized with tremours and convulsions, became pulseless, the lips livid, frothed at the mouth, and the pupils dilated to the greatest possible extent. The moment the occurrence happened, the finger was placed on the mouth of the wounded vein; and the operation being suspended, the patient seemed to revive from the effects of diffusible stimuli, and partially roused. The operation was then resumed, and very soon completed. The patient, however, expired without a struggle, before he could be removed from the operating table.

That this patient died by the *introduction of air into the cavity of the heart* there can be little doubt, and this candid narration of the facts should teach us the imminent danger of opening veins in the vicinity of the heart; and the knowledge of this danger may save many lives, which might otherwise be lost by a similar casualty. It is unfortunate that the case reported by M. Dupuytren, of a similar operation with the like result, has not been noticed in our standard works, else still greater caution might have been used in this case. Dr. March informs me, that Professor Stevens, of this city, had well nigh lost a patient from the same cause, while operating on the neck; and Professor Mott had to abandon an operation in consequence of this occurrence, the convulsions were so alarming. This patient, however, as well as that of Professor Stevens, recovered.

Dr. March, the operator in the unfortunate case here detailed, has since tried some experi-

ments on inferior animals; and among others, he introduced a blow-pipe into the jugular of a cat, and a single puff of the breath resulted in convulsions and death; and on dissection, the right side of the heart and larger veins were found filled with air. His experiments on this subject may be of the highest practical importance; and the explanation of the remarkable phenomena which followed the wounding of the vein in this and other cases, is a physiological problem, the solution of which, if accomplished, will be of the deepest interest to the profession and to humanity.

Dr. J. C. Warren has published an invaluable work on Tumours, which, in point of variety of pathological and surgical information on this topic, is superior to any other in the English language. This distinguished surgeon has twice removed the parotid gland, and in twelve cases dissected out lymphatic glands from the parotid region. He has removed forty-four submaxillary glands, two sublingual; and twice has extirpated one half of the thyroid gland. He has also successfully removed four tumours from the vagino-rectal septum.

Dr. G. W. Norris, of Philadelphia, relates an interesting case of pulsating tumour in the head of the tibia, in which the femoral artery was tied without permanent benefit. For this case, and an accurate account of the pathological appearances, see Amer. Journal, No. 50, p. 283.

Dr. A. H. Stevens, of New York, has published a clinical lecture on the operative surgery of tumours, abounding in discriminating precepts of practical character, the result of his extensive opportunities in public and private practice, and of his unrivalled success in this department of surgery. His two rules for guidance in the extirpation of solid tumours, which he very properly urges in this lecture, should ever be present in the mind of the young surgeon, viz.: 1st. Cut down to the tumour before its dissection is commenced; and, 2d. Remove the whole of the tumour and nothing more. In no department of the art is there more blundering surgery, and disreputable mal-practice, than in the removal of tumours by surgeons who have failed to learn, or neglected to observe these rules. By adopting the first rule, I have seen a tumour removed from the axillary region, and the plexus of nerves, as also the axillary vessels, artery, and vein, were completely exposed, while, by keeping close to the tumour they were all avoided, though in intimate proximity, and no secondary hemorrhage followed. The unsurgical ambition to perform such operations quickly cannot be too highly reprobated, and tumours, especially, should never be extirpated in a hurry, for that which is well done, is soon enough done. Dr. Stevens has never taken up the carotid artery, in the removal of tumours from the neck, and doubts if it is ever necessary.

By observing his rules, he has removed a large tumour beneath the mastoid muscle, which embraced the ninth pair of nerves in one part, and the common carotid artery, the internal jugular vein, the par vagum, and œsophagus in another part, without wounding either of these important structures. In several instances he has left the important nerves and blood-vessels bare, except covered by their sheath, from the sternum to a point above the bifurcation of the carotid artery, and has never known secondary hemorrhage or sloughing to follow, the sheath of these vessels and nerves being sufficient for their nourishment.

Dr. Geo. M'Clellan, of Philadelphia, has removed the entire parotid gland nine times successfully, and in a majority of the cases the patients have had no return of the disease. He restrains the hemorrhage by tying the external carotid, under the digastricus, and in the course of the operation has found it necessary to tie the internal maxillary and the temporal. He tied the common carotid twice in these cases, but does not think it either necessary or expedient. He has removed parts of this gland in multiplied cases, when involved in tumours. He has five times removed the one half of the thyroid gland, and in one case removed this gland entirely. In this instance, after tying both the superior and inferior thyroid arteries on both sides, he restrained the oozing of blood by the use of one of Hull's trusses, one pad being placed upon the spine, and the other over the wound, and relying upon the spring of the instrument for compression, which he finds does not impede respiration.

Dr. J. Mason Warren has followed the example of his illustrious father in encountering formidable tumours, and with the like success. He has removed four large tumours from the neck; two large submaxillary glands, and two large tumours from the groin, which closely resembled hernia in their form and locality. In all these cases the operations resulted happily.

Drs. Mott and Bush, of New York, Dr. N. R. Smith, of Baltimore, Dr. Mussey, of Cincinnati, Dr. Warren, of Boston, and many other surgeons in America, have successfully removed tumours including in their structure the entire parotid gland. But to Dr. M'Clellan, of Philadelphia, belongs the merit of being the first surgeon in the United States to perform this operation, which he did in 1826. His patient, Dr. Graham, is now living in New York, and in excellent health. Since the operation, he has visited Europe, and submitted himself to the examination of Sir Astley Cooper and Mr. Abernethy, both of whom were satisfied that the whole gland was removed.

Some doubts have been expressed as to the practicability of the removal of this gland, particularly by Dr. Gibson, of Philadelphia, who insists that it is a physical impossibility, and of course he doubts the accuracy of the reports of surgeons who have claimed success in this operation, whether among the ancients or the moderns.

The evidence, however, must be regarded as conclusive, that in some cases the entire parotid has been removed, as in Dr. M'Clellan's first case, already alluded to. And yet there can be little doubt that in many of the cases reported as extirpation of the parotid, only a portion of the gland has been removed, while in others the tumours extirpated, though occupying the parotid region, have not involved this gland, and these are the cases which have furnished ground for skepticism in relation to others in which there can be no rational doubt. The case of Mr. Bell, as reported in his work on Tumours, is even more than doubtful, and on this case it is that Dr. Gibson predicates his opinion, that the operation is impracticable.

That tumours of the lymphatic glands, superficial to the parotid, do often fill the parotid region is now well understood, and in many cases, by their gradual growth and pressure, they may even obliterate the parotid gland, cause its entire absorption, and completely occupy its situation. The removal of such tumours, extending deeply behind the jaw and filling the entire lo

cality occupied by the parotid in the normal condition, may be honestly mistaken by the surgeon for the extirpation of this gland. And, indeed, that such is the case in several of the instances reported, is manifest from the fact that the hemorrhage has been inconsiderable, and the external carotid has not been encountered in the operation; this, with other large vessels and nerves, having been obliterated by the pressure of the tumour. The morbid anatomy, in the displacement of the parts by tumours, often throws great obscurity upon such cases. The history of the disease, its obvious commencement in the parotid itself, and the tumour in such cases retaining the locality and configuration of the gland, and suspending or disturbing its function from the beginning; all these circumstances are essential to a true diagnosis. And it is only in such examples that any surgeon can demonstrate that he has extirpated this gland, even after removing a tumour from its seat. Dr. Warren, in his work on Tumours, distinctly recognises this discrimination.

Dr. N. R. Smith, of Baltimore, is of opinion that tumours composed exclusively of the parotid gland, though commencing deep behind the ramus of the jaw, do nevertheless sometimes escape from this confined situation; and as the superficial structure of the gland and its facial portion become involved and enlarge, the whole diseased gland protrudes, elongating the vessels and other posterior attachments, so that it finally becomes pendulous. In these cases he thinks the removal of the entire parotid has been effected with great facility and without danger. In such circumstances he has removed the entire thyroid gland, and found the superior and inferior arteries so elongated by the pendulous tumour, that they have scarcely required the ligature, the gland being nearly detached from its normal attachments. Under such circumstances the operation of removing the entire parotid or thyroid gland would involve neither difficulty nor hazard.

Professor Parker, of New York, has reported in the New York Med. Gaz., for Jan. 1842, a highly interesting case of encysted tumour in the mamma of a woman, occurring during lactation. It was of enormous size, and he punctured it with a trocar and drew off three quarts of milk. The operation was repeated twice afterward. It appeared to have originated from a closure of some of the lactiferous ducts. The same surgeon has removed two encysted tumours of cretaceous structure. In each case the tumour was of considerable size, and situated upon the arm of a young lady. The cysts being opened, their contents were found to be of the consistence and appearance of chalk.

Dr. Alex. E. Hosack has succeeded in curing scirrhous tumours of the parotid gland by applying a ligature to the common carotid. Two of his cases, under my own observation in this city, have been entirely removed by absorption, which commenced immediately after the ligation of this artery, and rapidly progressed until every vestige of the tumours has disappeared, though they were frightful deformities by reason of their great size. A third case is now under treatment, the operation having been performed, and the absorption having visibly commenced.

His success would seem to encourage a preference being given to this comparatively simple operation, instead of the hazardous and formidable remedy of excision or extirpation of the gland. It might with propriety be always resorted to first, and time enough elapse to ascertain its effect before extirpation be attempted. See Gibson's Surgery, last edition, and New York Lancet for 1842.

Dr. Alban Goldsmith, of New York, removed the parotid gland seven years since for an enormous hypertrophy of that structure, and the disease has never returned. By keeping close to the tumour he avoided all the large vessels, had occasion for no ligature, and the hemorrhage was inconsiderable.

Dr. W. C. Wallace, an eminent oculist of New York, has extirpated the lachrymal gland for an encysted tumour occupying this structure, and which had attained an enormous size. The patient recovered, and thus far there has been no return of the disease.

On the 29th of April, 1842, Dr. Mott removed an adipose sarcoma of a dense nature weighing about three pounds, from the scrotum of a boy named Hancock, aged two and a half years. The tumour first made its appearance two years ago, at the external abdominal ring, simulating the character and leading to the suspicion of the existence of a hernia. On cutting down, the tumour was found to be situated in the walls of the scrotum, between the fibrous coat and the tunica vaginalis, and so closely connected to the cord, as high as the pillars of the external ring, as to form a groove for its passage. The wound healed by the first intention, and the boy returned home well.

Dr. Mott has successfully removed the parotid gland entire; in one instance, for melanosis of this structure, taking the precaution of tying the external carotid. The disease, however, returned in other parts of the body, and ultimately destroyed the patient. He concurs in the opinion, that this gland is not very frequently the subject of disease, although occasionally found, as in this example. The lymphatic gland, situated on the parotid, is much more frequently the seat of scirrhous and other tumours. He has frequently removed this gland under such circumstances, and in two instances it had become as large as two fists. In these cases, he has found the parotid partially absorbed by the compression, so as to leave the ramus of the jawbone exposed, when the tumour is removed; and he has often seen the portion of the parotid remaining in a perfectly natural state. These cases are often confounded with tumours of the parotid, and are removed successfully, when the operation is supposed to include the parotid gland. So also with tumours of the socii parotidis, the removal of which is easily effected, as Dr. Mott has found in numerous instances.

In one case, he found an encysted tumour, containing a thin fluid, and being situated within the parotid gland; this was enlarged to three or four times its size. On laying the gland bare, he found its aspect to be perfectly normal, which led him to cut into it, when the sac presented itself in the body of the gland, surrounded by its healthy structure. This being removed, the patient readily recovered. The young surgeon should here learn, that when the structure of the gland is natural, he should cut into it instead of attempting its removal. Dr. Mott has removed the sub-maxillary gland in a patient in whom it had reached the size of the fist, and the tumour was of scirrhous hardness and ulcerated. In enormous tumours of the thyroid gland, he has twice tied the superior thyroid artery, and several branches of the inferior, with

decided benefit, and very considerable atrophy followed the operation. In one of these cases the sufferings of the patient, by the enormous magnitude of the tumour, became so great, that at his urgent solicitation, Dr. Mott was induced to exsect the whole gland, after its dangers were fully explained. The operation was performed, and the patient died from secondary hemorrhage. The tumour weighed six pounds.

In Professor Gross's late work on Pathological Anatomy, vol. ii. p. 170, some account is given of a tumour of the parotid gland, which had attained an enormous size, and which seems to have consisted of a fatty degeneration of that organ. Its extirpation was successfully performed by Professor Parker, now of the College of Physicians and Surgeons, in New York, and the patient completely recovered, with the exception of the partial paralysis of the side of the face. In this case the removal of the entire parotid was necessary, involving the division of the duct of Steno, and the portio dura, and requiring the ligature of the external carotid and three other arteries. The excavation exposed the styloid process of the temporal bone and its muscles, and yet the wound granulated kindly, the ligature coming away on the 16th day, and the patient was discharged cured in four weeks from the date of the operation. The tumour is preserved in the museum of the College, in New York.

Professor N. R. Smith, of Baltimore, reports a highly interesting case of the successful removal of a tumour involving the parotid gland, accompanied with practical remarks, and his personal testimony to the removal of the entire parotid gland, by Professor M'Clellan, of Philadelphia, in an operation of which he witnessed the performance. He also mentions the same merit as due to the late Professor Davidge, of Baltimore, Professor N. Smith, of New Haven, and Professor Dudley, of Kentucky.

Dr. J. Randolph also extirpated the parotid in 1838, with entire success. (See Amer. Jour., for 1839.—Reese.]

U.

[URETHRA. Before speaking of some diseases of the urethra, I will request the reader's attention to a few points of surgical anatomy, very necessary to be well understood by all who have occasion to pass instruments into this passage. From certain facts, specified by M. Malgaigne, it appears, that when the penis is lifted up, but not extended, a catheter has only to pass at most seven French inches and a half, when it will enter the bladder, and that a catheter, which is allowed to remain, will project at least an inch into the bladder, if it has passed to the extent of seven French inches. (See also *Velpeau, Anat. Chir.*, t. xxi. p. 234, 8vo, Paris. 1838.) The length of the prostatic portion of the urethra is variously estimated, from six to ten lines, (*Malgaigne;*) twelve to fifteen, (*Ducamp;*) eight to eleven, (*Lisfranc;*) that of the membranous, or muscular portion, from five to eight lines, (*Malgaigne;*) nine to ten, (*Ducamp;*) and seven to eleven, (*Lisfranc.*) "Its extent is not the same superiorly as inferiorly. Here it is very short, limited in front by the posterior extremity of the bulb, and behind by the prostate; so that superiorly its length is about an inch, and inferiorly, four or five lines." (*Benjamin Phillips, On the Urethra, &c.*, p. 11.) The spongy portion is subject to the greatest variation, and is the only part of the urethra, in which the different positions and the extension of the penis make a change. In the relaxed stage of the organ, there is an angle in the spongy portion of the canal, corresponding to one of about 45°, which is effaced during an erection. Reckoning from beneath the symphysis of the pubes, the two other portions of the urethra ascend obliquely backwards, so that the vesical orifice of this canal is three or four lines above the level of the arch of the pubes, and one inch behind the symphysis. M. Malgaigne also states, that when a straight catheter had been introduced into the bladder of a dead subject, laid out upon a table, the instrument described, in relation to the ground and the axis of the body, an angle of about 45°. When the penis is raised, as during an erection, the angle in the spongy portion is effaced; but the curve in the membranous and prostatic parts remains unaffected.

The direction of the canal, when the organ is quiescent, has been usually compared to the letter S; and Mr. Benjamin Phillips believes, that this may be nearly correct when the bladder and rectum are distended; "but when the penis is placed against the abdomen, there is found only one curvature, and this almost disappears when the bladder and rectum are undistended. If we place the penis in a direction nearly at right angles with the ideal axis of the body, and look at the urethra in that portion of its course which has not reached the symphysis of the pubes, it will be seen that it forms a curvature, which presents its convexity inferiorly; and that, after arriving in front of the pubes, the direction of the canal presents a straight line. When the corpora cavernosa are healthy, we may remove all curvatures with the exception of the first. In order to attain this end, M. Amussat has recommended, that the position of the penis should be such as to form with the axis of the thighs (the patient being in the erect position) an angle of 40° to 45°." (*On the Urethra, its Diseases, &c.*, p. 17.)

The urethra, then, is far from being straight; but it may be rendered so. The parietes of the urethra being soft and yielding, it is capable of being dilated to a certain degree. If its lower side then be depressed, by means of any solid instrument, to the level of the root of the penis, and its upper side be brought by the same instrument below the symphysis of the pubes, the angle in the spongy portion, and the curve in the rest of the canal, must both be at once obliterated. But, in order that the root of the penis may be thus depressed, M. Malgaigne observes, that its suspensory ligament, which connects it to the symphisis of the pubes and to the linea alba, must be loose; and that, when the penis is attached higher than usual, or the symphysis descends lower, greater difficulty is experienced in rendering the urethra straight. The same thing occurs when the prostate gland is in a state of

enlargement, which carries the vesical orifice of the urethra above its natural level. This is well represented in two plates of Stanley's work on Lithotomy. In two subjects, having hypertrophy of the prostate, Mr. B. Phillips ascertained the level of the most depending portion of the prostatic part of the urethra to be from six to seven lines and a half below the level of the vesical orifice of this canal; whereas, in healthy subjects, he found it to be only from three to five. (*Op.* cit., p. 18.) The spongy is the most dilatable portion of the urethra; but as any yielding of it upwards is prevented by the corpora cavernosa, between which it is lodged, the dilatation is almost entirely at the expense of its lower side, and admits of being carried to the greatest degree at the bulb, where the spongy substance is most abundant. At this point, corresponding to one almost directly under the symphysis, the canal suddenly becomes narrower at the commencement of its membranous portion. Afterwards, it enlarges again in its prostatic part, but here its floor has two lateral grooves in it, occasioned by the projection of the verumontanum in the middle. At the entrance of the bladder, there is also on this same lower side of the canal a transverse prominence, formed by the substance of the prostate gland, and a few fibres of the sphincter, which prominence is termed by M. Amussat the *pyloric valve*. The upper side of the urethra being everywhere smooth and firm, presents no obstacle of this kind.

Hence it is manifest, that when the beak of a catheter is inclined against the lower side of the urethra, there are two stoppages, as it were mechanical ones, and met with even in the dead subject; but there are two others which exist only in the living body, and which depend upon the contraction of the sphincter vesicæ. Such, according to M. Malgaigne, is the urethra of the adult male subject. In the child, the difficulties are less; the penis is less raised; the symphisis of the pubes does not descend so far; the prostate is nearly flat; the corpus spongiosum is but little developed; and the lower side of the urethra is so firm, that, until the age of twelve or fifteen, scarcely any obstacle is felt in the whole course of the canal. In an old man the reverse is the case: the corpus spongiosum, which is looser, admits of being depressed further towards the bulb; the prostate gland is frequently enlarged; and what M. Amussat calls the *pyloric valve* more strongly marked. From all the foregoing circumstances, it follows, that, *cæteris paribus*, it is more easy to sound, or pass an instrument into the bladder of a child, than an adult, and an adult, than an old person. (See *J. F. Malgaigne, Manuel de Méd. Opér.*, p. 330, ed. 2, 12mo, Paris, 1837.) In children, however, for reasons stated by all anatomists, and particularly noticed by Mr. B. Phillips, the urethra is more curved. (*On the Urethra, &c.*, p 19.) The male urethra being long and narrow, having also the angle and curve in it above described, and being surrounded by the prostate gland, and other parts whose diseased states are liable to interrupt the functions of this canal, we cannot be surprised at the fact, that it is subject to more numerous, as well as far more serious diseases, than the short, capacious, and simple urethra of the female. Thus, as an able surgeon remarks, "a mechanical obstruction to the flow of urine through the male urethra may arise in various ways. There may be an enlargement of the prostate gland, by which one extremity of the urethra is surrounded; an abscess in the perinæum; or one of the mucous follicles may be inflamed, and converted into a solid tumour; and any one of these, as well as some other causes, may operate so as to produce the effect. The most common cause of difficult micturition, however, is a contraction or stricture of the urethra itself." (*Sir Benj. Brodie, On Dis. of the Urinary Organs*, p. 2, ed. 2.)

Mr. Benjamin Phillips does not concur in the opinion that the membranous portion of the urethra is the most frequent seat of false passages, and he maintains that it possesses much solidity. "False passages (he observes) are less frequent here, than in the bulbous portion of the canal. (See also *Velpeau, Méd. Opér.*, t. iii. p. 908.) The reason of this must be immediately evident: false passages are ordinarily made in consequence of the difficulty experienced in the endeavour to pass an instrument through the strictured portion of the tube. Stricture is most frequently seated at the point of junction between the bulbous and membranous portions of the canal; consequently the false passage will be usually anterior to this latter point." (*On the Urethra, its Diseases, &c.*, p. 15. See also *Velpeau*, vol. cit., p. 910.) "*Aussi est ce bien plutôt à son entrée, à son départ du bulbe, que sur elle-même, qu'on observe les déchirures et les perforations traumatiques.*"

In the articles Catheter, and Urine, Retention of, I have noticed the advice of Sir Benjamin Brodie and of M. Velpeau, to keep the back of the catheter, staff, or sound, against the upper side of the urethra. "This side of the urethra, forming the concave margin of the segment of a circle, is, on this very account, shorter than the other, and less disposed to wrinkle. Having no excavation, and being closely adherent to the lower surface of the penis, it presents in its spongy part great regularity, and is so strong as not to be in danger of injury from the catheter." There is, however, as M. Velpeau explains, a small portion of the upper side of the urethra almost naked, just in front of the symphysis, where the corpora cavernosa diverge from the bulb to be inserted into the rami of the ischium and os pubis; and where the beak of the instrument, if carelessly pushed on, may do mischief. (See *Velpeau, Méd. Opér.*, t. iii. p. 907.)

This subject has not been overlooked by Mr. Benjamin Phillips. "In introducing an instrument into the urethra or bladder, (says he,) it is necessary to recollect, that the two opposed parietes of the urethra—the superior and inferior—differ singularly as to their configuration, and that we cannot indifferently follow the one or the other with the beak of an instrument. The inferior portion is yielding; for, neither along the penis nor at the height of the scrotum, nor beneath the pubic symphysis, is it supported by anything solid. In gliding along the canal, the beak of the sound may easily push before it the lining membrane of the urethra; for, along its surface, we meet in old men with inflections of the membrane, resulting from its flaccidity, which occasionally have a tendency to arrest the progress of the instrument. Some orifices of mucous follicles, and, among others, those of the glands of Cowper, are, according to general opinion, susceptible of receiving and arresting the beak of a sound, especially if it be of a small size. Lastly, at the level of the bulb, and in front of the contour of the neck of the blad

der, on the sides of the verumontanum, there exist on the inferior surface marked depressions, the orifices of which are presented towards the external orifice of the urethra; against these the beak of the sound passes, and by them is occasionally prevented from making further progress.

"If we examine by means of dissections (attentively made) false passages formed in the urethra during life, or after death, in subjects submitted to catheterism, we find, that they are produced by the rupture of the inferior parietes of this canal, and that the greater number of those passages exist either at the situation of the depression I have pointed out, or at the bulb. The disposition of the superior part of the urethra is infinitely more favourable, as a conductor for instruments, than the inferior. Sustained in front by the corpora cavernosa, and behind by the pubic symphysis, it presents great firmness: and we find only longitudinal replications, which are removed by the distention produced by the instrument; and no obstacle is here presented to its progress. No depression exists here under ordinary circumstances. There is no projection of the prostate into this portion of the tube; neither do we find many follicles, either isolated or grouped; nor any considerable orifice." (*On the Urethra, &c.*, p. 129.) For additional remarks, see CATHETER, and URINE, RETENTION OF.—C.]

[Dr. Alex. E. Hosack, of New York, has called the attention of the profession to a peculiar affection of the female urethra, consisting of sensitive tumours of a florid red colour situated within the meatus, and covered by the delicate lining membrane of the urethra; and demanding surgery for their relief. He describes them as exquisitely sensitive, and bleeding upon the slightest touch.

They resemble a split pea, varying from that to the size of a small kidney bean, and are placed upright in such a manner as to break the flow of urine. The patient does not complain of the pain of urinating as her greatest distress, for it is not to be compared to that caused by exertion, or from contact of the dress, which is frequently excruciating.

These tumours are attached usually to the margin of the urethra, from which they can be readily snipped off with the scissors; they are liable, however, to return, and the margin of the urethra assumes a fungoid appearance, with the same highly organized structure. In some instances it appeared as if the living membrane had shot out like a fungus, or was prolapsed, under which circumstances the doctor is in the habit of excising a portion of the urethra, say from half an inch to an inch from the external orifice.

The steps of the operation consist in first measuring the length of the urethra by the introduction of a female catheter, and marking it the instant the urine begins to flow; the fungous excrescence is then snipped with the *pince* of Musieux and drawn out.

The urethra is next circumscribed with a knife, carrying on the dissection until you arrive at sound structure, when you make a transverse section of the whole. The hemorrhage at the moment is excessive, but by pressure it is always arrested. The patient is usually troubled with retention of urine, making it necessary to have the water drawn off. This inconvenience may be obviated by leaving an instrument in the bladder for the first day or two after the operation.

This disease is spoken of by Morgagni in 1751, afterwards by Mr. Hughes, in Gloucestershire, in 1769, and also by Mr. Wardrop in the London Lancet, vol. 13; by Boyer in his Surgery, Sharp, Warner, and Jennen Chaussier, and Dubois, Madame La Chapelle, Rosenmuller, Vogel, Kaldibrand, and Prochaska.

Dr. A. E. Hosack arrives at the following conclusions respecting this disease:—

First, that the disease is characterized by peculiar symptoms. Second, that it is not confined to any age. Third, that it is unaccompanied with discharge unless the parts are chafed or abraded. Fourth, that in order to prevent a return of the disease it is better to remove at once the external orifice of the urethra, including the tumour. Fifth, that it is a complaint of slow growth, and does not attain to any great size, for in no instance yet recorded, so far as I am enabled to learn, has it been found larger than a small cherry.

Dr. Parker, of New York, has lately performed the operation of excising these tumours from the female urethra with success.—REESE.]

[URETHROPLASTIC. The application of the autoplastic method to the cure of fistulæ, fissures, and ruptures of the urethra, has been successfully made by Drs. Mott, Mutter, Detmold, M'Clellan, Pancoast, and many other American surgeons.—REESE.]

[URINARY CALCULI. A highly interesting case has lately fallen under my own observation, in which upwards of a hundred calculi have passed at different periods through the urethra, varying in size from that of the head of a pin to that of a large sized grain of coffee. Seventy-three of these calculi are now in my possession; and as the patient is under my personal observation, and more are passing every week, I can vouch for the facts here recorded, and shall report to the profession the progress and the result of the case in one of our periodicals.

The colour of these calculi is a yellowish brown, very smooth on their surface, and for the most part have a concavity on one side, and a convexity on the other; which, with some pains, may be accurately fitted one to the other, in the same order and relation in which they may be supposed to lie when in situ.

These calculi resemble very much those lithic concretions which are so often discharged from the bladder, and are liable to be mistaken for these. On analysis, however, they are found to contain only phosphate of lime, without a particle of lithic acid or ammonia. The valuable paper of Dr. Wollaston, in the *Philosophical Transactions for* 1797, furnishes us with this test, by which to distinguish the *calculi of the prostate gland* from those of the bladder and kidneys; and by this and other criteria, there can be little doubt but the concretions in this case have existed in the prostate gland; whence, so fast as they are dislodged, they get back into the bladder, or forward into the urethra, and then pass off with the urine.

The history of this case is highly important, and from the patient I collect the following facts: He had been of a hale, vigorous constitution, without any symptoms of this affection, until about four years since, when he was 61 years of age. He was then attacked suddenly by a suppression of urine; frequent inclination, but no ability, to empty the bladder; pain so

URINARY CALCULI.

excruciating, as to disable him from his work and from walking. He at first resorted to Harlem oil, and by the advice of his physician, drank mucilaginous teas of various kinds made of rain-water; the disease being supposed to have originated from the pump-water heretofore used. Soon after this excruciating torture came on, while drinking gin to a great extent, with the hope of finding relief by this means, he observed for the first time, that whenever the urine flowed, small calcareous concretions of a yellowish colour, of the shape and size of radish-seeds, passed through the urethra. Having collected a tea-spoonful of these little stones, he submitted them to a physician for examination; by whom he was sent to a distinguished surgeon in this city, that he might undergo the operation of sounding. The sound having been introduced, and the presence of calculi having been detected, he was told that the operation of lithotomy could alone afford him any relief.

From his advanced age, he declined to submit to the operation, and gave himself up to a lingering death. As, however, no relief was obtained from the diluents or diuretics which he had been so long using, and as he began to feel that the gin was doing positive injury, he resolved to discontinue the use of them all, and begin to drink pump-water, from which he had been deprived by medical advice, and then, as he expresses it, "trust in the Lord for life or death."

In about three weeks from the time in which he thus gave up all medical treatment and drank freely of cold pump-water, he observed a small stone to drop into the urinal, and in a few days another; each affording him some relief. Since that time, which is now a little more than eighteen months, he has passed all these, and many more which have not been preserved. He says that one passes every four or five days, and sometimes two at once; and he is conscious of the passage of each, although the pain is very slight. Since these calculi have been passing, he has been rapidly recovering his health and bodily strength; and from a spectacle of emaciation, he is now a strong, robust man, and at his age has extraordinary health. He has now no difficulty in passing his urine, except sometimes when a momentary interruption occurs to the stream, by one of the stones passing into the urethra; when it is soon forced out with very little inconvenience.

He is impressed with the belief that these are fragments of a large calculus in his bladder, which was felt by the sound; and that since he ceased to trust in human power, it has been miraculously broken, and that he is now convalescent by supernatural agency. He is perfectly happy under this conviction: and the propriety of dissuading him from this view of the subject, or convincing him that natural causes will account for the comfort he enjoys, is exceedingly questionable.

But while we leave the patient himself undisturbed in the enjoyment of his faith, the medical philosopher cannot fail to discover in the progress of this case, as narrated by the patient, and in the results of which he is now in possession, details presenting some most important and interesting features, which may be improved for practical purposes.

That these calcareous deposites have never been larger than they now are is clear from their smooth surface, and from their peculiar organization. That they did not originate in the bladder or kidneys may be deduced from the fact already named, that they do not contain an atom of the lithic acid. And that they could exist at all in the bladder in this quantity for any length of time is improbable, from the fact that so soon as one of them gets into the bladder, it produces uneasiness until it is discharged, when the relief seems to be entire.

The probability is, that when he was sounded by the surgeon, one or more of these calculi had passed into the bladder from the prostate gland in which they were imbedded, either in the enlarged cells of the gland, or encysted, as they are sometimes found. These were felt by the sound; and as the rest produce ulceration, they pass one or two at a time into the bladder, and so out through the urethra.

Had this patient submitted to the operation of lithotomy, and the calculi been removed, it will be readily perceived that no permanent or satisfactory relief would have been obtained; for to remove them from the body of the prostate is altogether impracticable. It is highly probable, therefore, that his refusal to submit to the operation has saved his life, although any surgeon would be liable to give the same opinion under similar circumstances. May we not safely presume, that many of the failures occurring in lithotomy occur under similar circumstances, the calculi originating in the prostate, and thence finding their way perpetually into the bladder?

In Marcet's valuable *Essay on Calculous Disorders*, much information on this subject will be found, together with a plate very accurately representing these calculi of the prostate gland. He states, that the symptoms are often mistaken for stone in the bladder; and if any of these calculi be discharged, their appearance is so similar to that of lithic concretions, that unless their chemical nature be ascertained, they will almost infallibly be mistaken for that species of calculus. He also records an instance of an error of the opposite kind, in the case of a foreign minister; who, while attended by one of the most eminent surgeons in London, passed a number of small brownish concretions, which were mistaken for calculi of the prostate, and the treatment was for some time conducted on that supposition. But upon subjecting these calculi to chemical analysis, he found them to consist of pure lithic acid; and upon an appropriate treatment being adopted, the complaint soon entirely disappeared.

Distinct from this affection, and requiring different treatment, a case may be mentioned which often occurs, in which the calculus, although formed in the kidney or bladder, becomes lodged in the prostate, in attempting to pass through the urethra. Sir Astley Cooper has recorded a case of this description, in which, upon attempting to introduce the catheter, he felt a grating sensation at the neck of the bladder; and on introducing the finger into the rectum, calculi could be felt moving in a cyst within the prostate, and a distinct clashing could be heard as their surfaces were pressed together. It was proposed that a small incision should be made through the rectum into the prostate, for the purpose of extracting the calculi; but the patient would not consent. This gentleman died a few years afterward, when the prostate was found to contain a number of calculi; and this was also the case with his kidneys, from which these con-

cretions had doubtless descended, and were arrested in their course.

Dr. R. Coates, of Philadelphia, has a statistical account of cases in the Pennsylvania Hospital, in the Amer. Journ. for 1835, which is valuable and useful for reference.

Professor Gibson has a valuable chapter on this subject in his late work. He mentions a singular variety of calculus found in the bladder by Dr. Physick, and since by Dr. Lemoyne, of Washington county, Pennsylvania. It closely resembled common plastering mortar, and consisted in both cases of sabulous matter and hair. In his own practice, Dr. G. removed a large stone by lithotomy from a boy four years old, in the centre of which was found the greater part of a needle, which had become the nucleus for a calculus, which thus early had attained the size of a small egg.

The case of the late Chief Justice Marshall, upon whom Dr. Physick performed the lateral operation of lithotomy a few years ago, is in one respect unique, viz., the number of calculi found in the bladder, which far exceeded that ever before reported. The most remarkable case on record is that in which 398 calculi were found in the bladder after death, but Dr. Physick extracted from the bladder of Chief Justice Marshall more than one thousand, varying from the size of a partridge shot to that of a bean, which were counted, besides many which were lost. They were uniformly of an oval shape, and upon the end of each was a black spot of the size of a pin's head. Notwithstanding the frequent introduction of the forceps and scoop, as well as the other precautions for completely cleansing the bladder, the venerable patient, who was of very advanced age, completely recovered, and for a number of years remained upon the bench he had so long honoured in excellent health.

Dr. Sewall, of Washington, has recorded, in the Boston Medical and Surgical Journal, an extraordinary case of hereditary calculous diathesis.

For the treatment of urinary calculi, Dr. Physick was in the practice of using the tincture of phytolacca, (pokeberry,) in doses of a dessert-spoonful three times a day, with or without ten or fifteen drops of spirits of turpentine. The Venice turpentine made into pills, to the extent of half a drachm in 24 hours, is recommended by Dr. Betton, of Germantown. These and the like remedies are useful when the patient is suffering from a fit of the gravel, or in anticipation of its recurrence, and which for the most part is dependant on the passage of a calculus along the ureter.—Reese.]

[UTERUS, CANCER OF. The disease generally first attacks the cervix, and especially the posterior lip or margin of the os tincæ. In the beginning, the symptoms are attended with ambiguity, and cannot be discriminated with any degree of certainty from those arising from various other causes productive of irritation of the womb. Most frequently the disease is ushered in by irregularity of menstruation, a sanious bloody discharge, or a profuse leucorrhœa; together with an annoying sensation of tension, weight, and dragging pains in the lumbar and hypogastric regions, extending frequently to different points of the pelvis and hip; frequent desire to make water; tenesmus; and lancinating pain in the cervix uteri. On examination, the portion of it towards the vagina is perceived to be either hardened at every point, or indurated in some places, and softened in others. The os tincæ is likewise indented, irregular, and half open. When pressure is made with the finger, a sanious bloody matter is discharged.

The disease may continue in this state for several months, or even years; but, at length, the symptoms become more aggravated; the darting pains, which now affect also the groins and thigh, occur with increased violence; and the discharge becomes exceedingly ichorous and fetid, blended with sloughy matter and clotted blood. Sometimes, as I have frequently noticed, profuse hemorrhages come on. At the same time, the constitutional impairment becomes more and more serious, and is accompanied by the carcinomatous hectic, and the pallid sallow appearance of the countenance, so characteristic of organic disease. Ultimately death takes place, either suddenly, from profuse bleeding, or, as more usually happens, the patient dies hectic, in a state of horrible suffering.

If, in this advanced form of the disease, a *post mortem* examination is instituted, the portion of the uterus connected with the vagina is found ulcerated, or more or less destroyed, and fungi, or indurated masses, extend from this point within the cervix. The uterus, or upper portion of the vagina, is frequently much hardened; and the ulceration may even be continued into the rectum and bladder, so as to form new communications between one or even both these viscera and the vagina, and account for the involuntary discharge of urine and feces by the latter passage.

When the disease commences in the cavity of the uterus, the cervix remains for a long while unaffected, while the body of the womb enlarges in every direction, and may attain considerable magnitude. In such a case, the swelling is sometimes distinctly perceptible through the parietes of the hypogastrium.

Cancer of the uterus may originate at any period after puberty, (*Chelius, Handb. der Chir.*, b. ii. s. 630;) but the time of life between the ages of 40 and 50, is that in which its commencement is most common. I have attended not less than three women, who died under the age of 30, from the effects of the cancer of the womb. Cruveilhier observes, that from the age of 35 to that of 50 is the principal season for this cruel disease, though he has known one woman of the town die of it, whose age was only 26; and has seen it in women as old as 60, 70, 80, and even 83. In University College Hospital, I lately had a case in a woman about 70, in whom it proved fatal, about two years after its first attack. In this case, the disease had implicated the whole of the vagina and even the labia. One young woman, whom I attended in Great Ormond Yard, for a cancerous womb, of which she died, had an aged mother, who had suffered severely from carcinoma of each breast, but had latterly been freed from the disease by a sloughing process; an event which is uncommon, but does now and then happen. (See Cancer.) Next to cancer of the breast, cancer of the womb is the form in which the disease most frequently presents itself. Sometimes the disease takes place in the womb and breast together; and Cruveilheir records an instance in which cancer uteri was accompanied by a medullary tumour in the substance of the left hemisphere of the brain, so that, in the latter stages of the case, the patient was attacked

with convulsions and hemiplegia. According to this distinguished pathologist, however, notwithstanding the tendency of cancerous diseases in general to affect the whole economy, by extending from the point first attacked, as from a centre, cancer of the womb is but rarely accompanied by this general implication of the system, and especially of the breast.

It appears also, from Cruveilhier's researches, that the vagina is as frequently the seat of cancer as the neck of the womb. "Its anterior paries is much more frequently attacked than its posterior; and hence it is rare to find instances in which the lower portion of the bladder does not participate in the disease." (*Anat. Pathol.*, liv. xxiii. pl. 6.)

Cruveilhier finds, that what he terms the *areolar pultaceous cancer*, is the most frequent of all the forms of cancer to which the uterus is liable. In this the uterus is transformed into a spongy texture, from which a cancerous substance, of greater or less consistence, may be compressed in the shape of small worms; so that, when this texture has been emptied by suitable preparation, a hollow cellular structure remains. Cruveilhier conceives that he has made out the fact, that cancer of the uterus begins in the venous system. However this may be, he notices another fact, which is of greater importance to the practitioner, viz., that the *lymphatic glands* in the *pelvis are almost constantly affected in cancer of the womb*. He specifies in particular two, situated, one to the right and the other to the left, at the sides of the pelvis, on a level with the highest part of the ischiatic foramen; these, he says, are often the only lymphatic glands implicated. The lumbar glands he finds less frequently diseased than the pelvic; and he states, that they may be enlarged and red without presenting any vestige of cancerous structure. The inguinal glands are only involved when the disease attacks the external pudenda, and the orifice of the vagina. In only one dissection he found the cancerous substance in the thoracic duct, though he examined it at every opportunity; and, in another instance, he traced the same substance in many of the lymphatics, which proceeded from the diseased parts. (*Op.* cit., liv. xxvii.) In one case, dissected by Cruveilhier, one ureter was enormously dilated, and the corresponding kidney wasted. "The relations of the ureters with the lateral and superior part of the vagina, and with the lower part of the bladder, which is often implicated in cancer of the uterus, account for the impediment to the flow of the urine through the ureters, the lower portions of which are often surrounded by cancerous masses, which compress them. This compression may take place in so great a degree, that the lower part of the ureter is completely obliterated; and, what is remarkable, such compression does not produce the fatal consequences which theoretically might be expected. The urine dilates the ureter, (see liv. xxvii. pl. 2, fig. 2,) which, at the same time that it becomes dilated, is lengthened and rendered tortuous or spiral, like a varicose vein. The pelvis and calices in their turn are also expanded, so as to acquire a considerable capacity. The kidney, compressed by the urine, accumulated in the dilated calices, gradually wastes away, and is converted into a mere shell, or husk of a pale yellow, having some resemblance in colour to the changed state of the kidney, known of late by the name of Bright's Disease; and such atrophy may proceed so far that no urine can be secreted, or so little, that any redundance may be easily prevented by absorption." The possibility of life continuing long, with an obstruction of both ureters, would be, however, a very different case from that described by Cruveilhier.

Gangrene, consequent to cancer of the womb, is found by Cruveilhier to be very common, sometimes destroying the cancerous structure layer by layer, and, in other instances, attacking the whole mass of it. In both cases, the discharge becomes horribly fetid, and when the finger is withdrawn from the vagina, it brings away a sloughy putrid detritus, which Cruveilhier says can be compared to nothing more like it than the substance into which hospital gangrene transforms the textures invaded by it. The sloughing may advance slowly or rapidly; a difference which has vast influence on the intensity and acuteness of the symptoms. When gangrene attacks the whole of the cancerous mass, and nearly annihilates it, the case might be mistaken for one of primary mortification; and, in many examples, the cancerous state of the pelvic and lumbar absorbent glands is the only criterion of the gangrene having been preceded by a cancerous affection of the uterus. (*Cruveilhier, Anat. Pathol.*, liv. xxiv.)

As I have never seen more than palliative relief derived from medicines or local applications, in the treatment of true cancer of the womb, I shall not dwell long upon this part of the subject. So far as my experience goes, temporary relief is to be sought principally in the judicious employment of narcotics and purgatives as occasion requires, the horizontal position, leeches on the hypogastric region in the early stage, fomentations, and frequent ablution with tepid water, or decoction of poppies. I have not generally found the chloride of soda lotion, nor any astringent injection, superior to tepid water in the temporary relief afforded; but when the discharge is copious and exceedingly fetid, they may be tried. The tincture of iodine, the hydriodate of potash, the iodide of mercury, the carbonate of iron, the liquor arsenicalis, the aqua laurocerasi, and almost all the medicines specified in the article CANCER, I have seen tried, but without any permanent benefit.

Modern experience proves, however, that when cancer, or rather scirrhus, is confined to the neck of the uterus, it will sometimes admit of being successfully removed by excision. The cervix uteri, in the healthy state, projects from three to six lines into the vagina; but M. Lisfranc has known it make no projection at all. The vagina around it is thin, and in contact, on one side, with the bladder, and, on the other, with the rectum; while upwards it is continuous with the proper substance of the uterus. The vagina may be detached from the cervix uteri to the extent of more than half an inch, without any *risk* of opening the *cul-de-sac* of the peritoneum which separates it from the bladder; but since the latter viscus adheres very intimately to its anterior surface, it might then be reached by the instrument. Behind, the peritoneum not only covers the corresponding surface of the uterus, but also descends over the vagina, to form what M. Velpeau terms the rectogenital excavation; so that, on this side, the knife, if carried only a few lines, would open the peritoneum. M. Velpeau considers it erroneous then to say that there is a space of eight lines in

front, and ten behind, between the upper edge of the cervix uteri and the serous membrane of the abdomen. The distance is stated by M. Malgaigne to vary, according to the greater or lesser projection of the cervix. M. Malgaigne also states, that the vagina may always be detached from the cervix to the extent of more than half an inch in front, without hazard of wounding the peritoneum; but, behind, the vagina ascends further, and there is less space between it and the peritoneum. It may be added, that no very large arteries, or veins, are distributed to the neck of the womb. (See *Velpeau, Nouv. Elém. de Méd. Opér.*, t. iii. p. 620; *Malgaigne, Man. de Méd. Opér.*, p. 747, ed. 2.)

According to Baudelocque, the excision of the cervix uteri was first suggested in 1780, by Lauvariot. M. Tarral even ascribes it to Talpius; but the tumours which the latter took away were, according to M. Velpeau, evidently polypi. Lazzari, who puts in a claim for Monteggia, is also believed to have made a similar mistake; nor has M. Velpeau been able to satisfy himself that the operation was ever performed by André-de-la-Croix and Lapeyronie, as M. Tarral represents. Troisberg recommended it, however, in 1787; and, as a critical writer observes, sometimes the cervix uteri was removed accidentally with the knife by ignorant persons, who mistook it for a polypus. (See *Edinb. Med. and Surg. Journ.*, No. 103, p. 377.) Professor Osiander, of Gottingen, first executed the operation in 1801, on a widow, whose vagina was filled by a very vascular fetid fungus as large as a child's head, growing from the orifice of the womb. By means of Smellie's forceps, the fungus was drawn down; but it broke off, and a tremendous hemorrhage ensued. The operator, without loss of time, introduced several crooked needles, armed with strong ligatures, through the bottom of the vagina, and body of the uterus, until they emerged at the os tincæ. These ligatures served to draw down the uterus, and retain it near the mouth of the vagina. Osiander then introduced a bistoury above the scirrhous portion, and divided the uterus exactly in the horizontal direction: for an instant, the bleeding was profuse, but it was quickly stopped by means of a sponge, saturated with styptics. In about a month, the woman recovered. Osiander afterwards performed eight similar operations upon different patients, all of whom are reported to have experienced a cure. The observations of Osiander were no sooner promulgated in France, than M. Dupuytren adopted the new operation, and made numerous trials of it. M. Recamier followed Dupuytren; so that by 1815, the excision of the cervix uteri had become in France a common operation. However, it remained for M. Lisfranc to extend the practice, and to convince the most incredulous of the little danger resulting from it. (*M. Velpeau, Nouv. Elém. de Méd. Opér.*, t. iii. p. 615.) Dupuytren also performed the operation eight times; but, instead of employing the ligatures and knife, as Osiander did, he drew down the uterus with hooked forceps, (*les pinces de museux*,) and divided it, above the scirrhous part, with curved knives and scissors. One of the patients, on whom Dupuytren operated, had a return of the disease, and submitted to a second operation with no better result; but was afterwards effectually cured by the application of caustic, with the aid of the speculum invented by M. Recamier.

Dr. John Brown, surgeon to St. Mark's Hospital, has published one of the best descriptions of the operation of removing the cervix uteri, as witnessed by him at Paris, in 1826 and 1827. To perform this operation, (he observes,) the patient must be placed as for lithotomy, with the parts exposed to a clear light. The speculum (that of M. Recamier, or that of Madame Boiven) is then to be introduced by a slight rotatory motion of the hand, its outside having been previously smeared with cerate or butter, in preference to oil, and care being taken to avoid soiling the interior of the tube, which, when clean, serves to reflect in its sides the disease of the cervix, and will of course aid the practitioner in forming his opinion. A lighted candle, held close to the larger end of the instrument, is sometimes employed with a similar view. The condition of the cervix having been ascertained, and the speculum withdrawn, the left forefinger is passed up, and on it the double hooks, which are firmly fixed in the projecting lips of the cervix, one on each side, and given to an assistant for a moment. The operator, then taking both hooks in his right hand, gradually and gently draws down the cervix, till it has been brought nearly on a level with the external parts; he next passes a button-pointed bistoury behind the diseased portion of the uterus, (the labia, &c. being held asunder,) and removes it. A similar operation is performed in cases of polypi, with this exception, that, in place of the bistoury, a large and strong pair of curved scissors is used, and that the neck of the polypus is in general alone divided. The cut surface of the uterus quickly resumes its natural position on the removal of the hooks, no dressing being commonly applied to the part; and the patient being put to bed, is placed on a strict regimen for several days, venesection and leeching being freely employed, not only to remove, but even to prevent attacks of inflammation. (M. Lisfranc usually bleeds his patients at La Pitié to ʒ x. or ʒ xii. soon after the operation, the effect of the excision being considered by him, particularly where there has been preceding menorrhagia, as analogous to a suppression of the menses; repeating the bleeding, leeching the sacral region, and using emollient fomentations and enemas on the least occurrence of abdominal tenderness. Such treatment is generally very successful, although it is not uncommon to bleed three or four times from the arm, besides applying leeches.)

After the simple introduction of the speculum, in certain cases where an inflammatory diathesis exists, (more particularly in young persons, or where the cervix, in addition to other disease, appears gorged with blood,) care is to be taken to throw emollient lotions, or those containing the chlorides of lime, or soda, into the vagina several times daily, by means of a syringe; and the wound, if tedious, may require to be touched with the nitrate of silver. Women, so treated, are usually able to go home in three or four weeks. It is not desirable that the patient should go to stool soon after the operation, as the effort might detach the coagulum from the wound. One woman is alleged to have become pregnant *fifteen days after the operation*, went the usual time, and was delivered in three quarters of an hour, as there was no cervix uteri to resist the passage of the infant. "When we consider (continues Dr. Brown) the high vascularity and great irritability of the uterine apparatus it

might be supposed that the operation just described must necessarily be of an extremely painful nature, and that troublesome hemorrhage would always occur. But no such consequences usually ensue; the drawing down of the organ being commonly effected by very slight efforts; and, as to pain, the patients hardly ever appear to experience any. The bleeding seldom exceeds one or two ounces. There is one consequence, however, which usually follows, and which, I need scarcely observe, requires to be energetically treated; I mean inflammation of the peritoneum. Whether this arises from the division of the portion of that membrane descending between the rectum and uterus, or from continuous sympathy, (as Hunter calls it,) or from an extension of the disease from the parenchymatous substance to the membranous covering of the uterus, is not easy to determine. The portion of the cervix removed is usually that which projects into the vagina, and no more; and it will, I imagine, be conceded, that when we consider the general extensibility of the organ, such a portion of it may be safely excised without implicating the important membrane in question; but I do not say that, on occasions where a portion of the *body* has been removed with the *cervix*, such an injury may not have been done; an accident which the practitioner should do his utmost to avoid." (See *Dr. J. Brown's paper* in *Dub. Journ. of Med. Science*, vol. vi. p. 22—27.)

In 1828, M. Lisfranc had performed this operation on thirty-six individuals, as is stated, for *cancer uteri*, the recognition of which last declaration as a positive fact, I beg to observe, is a matter of great importance in determining the merits of the operation. Of the thirty-six patients thus operated upon, "thirty were then well, three dead, and three in progress of recovery. One female, operated on some years before, had since become pregnant, and recently given birth to twins. Lately, at the Hôtel Dieu, the entire uterus has been removed by M. Recamier; and, in September last, this formidable operation was performed at La Charité, by M. Roux. The patient died in twenty-four hours after the operation." (See *Practical Formulary of the Parisian Hospitals*, by F. S. Katier, p. 17.) Langenbeck's extirpation of the whole uterus, by cutting through nearly the whole of the linea alba, I do not deem it necessary to detail, as it is a proceeding which I would never recommend to be imitated. The poor woman experienced the same fate as the patient of M. Recamier.

Even with regard to the excision of the cervix uteri, it is perfectly manifest to me that many of the cases in which it was performed were not truly cancerous. Doubts may be entertained, I think, whether the enormous tumour removed in the very first instance of such operation by Osiander, was really a cancerous affection. Several of the cases operated upon in Paris, were decidedly not of this character. On this point I fully agree with Dr. Brown, an eye-witness, who remarks: "While I admit the facility with which such a measure may be accomplished, I must be permitted to doubt its necessity in some of the cases related. The second and third were, in my opinion, such affections as would have yielded to common local and constitutional measures, and would, I have no doubt, have been so treated by British surgeons, and perhaps by a few of our French brethren." (See *Brown*, in *Dublin Journ. of Med. Science*, vol. vi. p. 29; and *M. Ricord's Obs. upon Ulcer of the Cervix Uteri*, in *Journ. Hebdomadaire.*) M. Velpeau, who regards the excision of the cervix uteri as an operation so completely established as to render unnecessary any reply to the arguments used against its performance by Wenzel and Zang, acknowledges that the difficult point is to lay down precisely the indications for it. "The elongation from simple hypertrophy of the neck, being rather an infirmity than a disease, never requires it. Excoriations, ulcers, syphilitic growths, not being of an incurable nature, are none of them cases for it. The same may be said with respect to the indurations and lumps, free from pain, whether attended or not by chronic inflammation, so often met with in females between the ages of thirty and forty. It is only, then, in well-marked cancerous disease, that the operation is allowable; but here is the difficulty of the question. In truth, so long as cancer is free from ulceration, or does not present itself in the upper part of the vagina, in the form of a more or less bloated mass, the diagnosis is exceedingly difficult. The firmness, or natural consistence of the cervix, the varieties in its size, protuberance, density, and form, according to the age and different conditions in which the female may be, demand, in the first instance, great ability, in order to prevent the belief in affections of which not a vestige exists. Then, how can there be any certainty of a lesion so deeply situated in the midst of so condensed a texture, and composed of elements so changeable? This is not all: when the existence of cancer is incontestable, its limits must still be ascertained. On this point, doubts are seldom quite removed, till the disease is far advanced; and scarcely ever can a guarantee be given that the cervix is the only part diseased, and the body of the uterus not yet attacked." However, encouraged by the fact, that the cancer of the uterus continues longer than that of other parts, without extending to the rest of the system, M. Velpeau would not absolutely renounce the operation. "It is better (says he) to try it than abandon the woman to a certain death, whenever the disease leaves a hope that the whole of it may be removed." (See *Nouv. Elém. de Méd. Opér.*, t. iii. p. 616.)

In one instance, Dr. Brown, in the attempt to remove the cervix uteri, tried to draw down the latter part: "For this purpose, (says he,) Boivin's speculum having been introduced, its blades were divaricated and held by an assistant; the hooked forceps were then passed through the tube, and fixed on each side of the cervix. Gentle traction was next exercised (the speculum having been withdrawn) upon the two forceps, which seemed to produce more uneasiness than is usual, till a considerable portion of the excrescence appeared within the blades. It was now found that the excrescence had been torn off from the cervix, and remained attached only by a portion of the lining membrane: this was divided by a blunt bistoury passed cautiously on the finger, and the tumour removed. Attempts were next made to fix the hooks into the lower part of the uterus, in order to remove the diseased surface from which the new growth had originated; but the instruments uniformly separated, from the parts being unusually soft. One of the forceps was at length passed into the os uteri, with a view to fix it there, *when a discharge of thick pus, to the amount of about one ounce flowed*; and, on passing up the finger, the inte

rior of the uterus appeared so unequal, (though not of stony hardness,) that further attempts to excise the cervix were considered unadvisable. The vagina was therefore washed out with cold water, and cold compresses applied; about two ounces of blood were lost. The uterus did not appear much enlarged." This woman recovered, and became free from all her previous ailments. The inferences deduced from this case by Dr. Brown are: 1. "That it may not be always practicable to excise the cervix uteri, or even to draw it down for that purpose. 2. That abscess of the uterine cavity may exist as a latent malady, without any decisive symptom to denote its presence. 3. That very great relief, almost amounting to a cure, may be afforded by the evacuation of such purulent depositions." (*Op.* et. vol. cit., p. 37.) The original disease appears to Dr. Brown to have been chronic inflammation of the cervix, ending in the formation of pus within the cavity of the organ, and accidentally complicated by the existence of a small excrescence. The absence of hardness and lancinating pain, he says, denotes that it was not cancer. The whole history of this case and its result confirm this view; and of course the case is another example in which the excision of the cervix uteri was not necessary.

Instead of the excision of the cervix uteri for cancerous disease, M. Bayle advocated the application of caustic; and his advice was founded upon the fact shown by pathological anatomy, that, in the early stage of malignant ulceration of this part, the texture of the uterus is healthy at the distance of two or three lines from the ulcerated surface. The patient having been placed in the right position, and the speculum introduced, the cancer is to be cleansed with dossils of charpie, introduced by means of a long pair of forceps. If the surface is irregular, or the seat of fungous granulations, they are to be removed with curved scissors, or a sharp edged kind of scoop, (Dupuytren.) In this manner, indeed, such growths may be removed, not only from the cervix, but from the interior of the uterus. After the ulcer has been cleaned, a roll of charpie is placed below the speculum, in order to protect the vagina from the action of the caustic. Then the caustic is applied, either the arsenical paste, (Bayle,) or the pure potash, scraped to a point, and fixed in a porte-crayon; or the acid nitrate of mercury, with which lint is wetted and conveyed with forceps to the ulcer. The application is continued for one minute; then copious injections of tepid water are employed for the removal of the uncombined particles of caustic; the charpie and speculum are withdrawn, and the patient put into a warm bath. In about four or six days, the application is to be repeated; and, if no ill consequences follow, it is to be continued at short intervals, but more and more lightly each time, in proportion as the cure advances. (*Lisfranc*; also *Malgaigne, Man. de Méd.*, p. 745, ed. 2.)—C.]

[UTERUS, POLYPI OF. The fact alluded to by Cooper, that polypus uteri has not the same tendency to return, when partially extirpated, that polypus nasi has; in fact, that partial extirpation, whether by the knife or ligature, is always followed by death of the portion remaining attached to the uterus, is very well illustrated by a preparation in the Obstetrical Museum of the College of Physicians and Surgeons, New York. The tumour was removed from the uterus of a lady, who had for three years suffered under the symptoms of polypus. The ligature was applied by Dr. Delafield, late Professor of Obstetrics in this college. The second day after the operation, on attempting to tighten the ligature, it broke, and the canula came away. Seven days after this the tumour was seized with a pair of strong lithotomy forceps, and, after slight rotation, was brought away. On examination, it was discovered that the tumour had not parted at the point where the ligature was applied, but that it had *peeled off* from the uterine mucous membrane about an inch higher up. The preparation now presents the body of the tumour, the neck strangulated by the application of the ligature, and above, an expansion terminated by a smooth surface, about the size of a cent, where the polypus was attached to the fundus uteri. This fact suggests the probability, that polypi of the uterus, like those of the heart, may at first be formed of detached coagula, which afterwards becoming organized, unite to the uterine parietes by simple adhesion. This hypothesis will account for the fact of their destruction by ligature upon any part of their structure, and their subsequent separation from the uterine wall, and coming away entire.

Professor Francis, of New York, inclines to an opinion similar to that of Professor Cooper, and is strengthened in this belief, from facts associated with a case of polypus at the fundus, which having been partially removed, pregnancy occurred subsequently, and no annoyance followed. There is no evidence of polypus at present existing, and the uterine functions are sustained with their wonted regularity.

Ample experience, according to Dr. Francis, of New York, justifies the use of iodine, both internally and externally, in a large class of uterine affections. No remedy, according to Dr. Francis, exerts a more general and salutary influence on this great viscus of the female economy. In cases of sterility or barrenness, its importance has been demonstrated in many instances; irregularities, arising from difficult menstruation, and the non-appearance of the monthly lustrum, have been overcome; in short, the hydriodate of potash, among other forms of iodine, is ever to be kept in mind in embarrassing cases of this nature. See also Francis's third edition of Denman's Midwifery.—Reese.]

[UVULA. The excision of the uvula, or a part of it, when elongated, is often necessary in cases of obstinate cough. It can often be accomplished with the scissors, but Dr. Physick constructed an instrument for truncating the uvula, on the same principle as that which he subsequently improved for excising the tonsils. The removal of the uvula has often been performed for stammering, when the impediment is ascribed to a narrowness of the passage, from the pharynx to the mouth, and in such cases the tonsils are often excised. Dr. Physick's paper on the subject is in the Amer. Journal, for 1827. Excision, both of the uvula and tonsils, has long been known to be useful in certain cases of deafness. Mr. Brain, a surgeon, of Manchester, has divided also the frenum epiglottidis.—Reese.]

V.

[VAGINA. Dr. Mussey, of Cincinnati, has twice succeeded, by dissection, in separating the walls of the vagina, which had adhered throughout their entire length. In each case, the adhesion was of four years standing.—Reese.]

[VARICOCELE. In this disease may be felt, in the course of the spermatic cord, an irregular swelling, consisting of several enlarged vessels, which swelling has a pyramidal shape, with the broad part towards the testicle, and the narrow part towards the abdominal ring. When the patient lies on his back, the tumour diminishes, or disappears altogether, because this posture promotes the return of the venous blood; but when the patient stands up it reappears, because the column of blood in the spermatic vein has then to ascend against its gravity. Moderate pressure with the hand will make the tumour disappear, not all at once, but gradually; and, when the pressure is taken away, the swelling reappears; not suddenly, but in a slow and gradual manner.

The spermatic veins, (M. Velpeau observes,) which are tortuous, undulating, very large, and to the number of two, three, four, or even more, are readily distinguishable down to the epididymis, and usually placed in front and at the sides of the other vessels. Long, soft, destitute of valves, continually dragged by the weight of the testicle, enveloped in loose cellular tissue, exposed to compression in the inguinal canal in consequence of the double bend which they make, and being also equally pressed upon in the iliac fossa in front of the muscles, by the end of the ileum, or the cœcum, on the right, and by the sigmoid flexure of the colon on the left, it is not surprising that the spermatic veins should frequently be the seat of varicose dilatation, and that a varicocele should become sometimes very large. The kind of knotty chain, which they then form, gradually enlarges as they approach the testicle, because their branches increase in number in proportion as they come nearer to the lower end of the cord. This fact proves, that in order to obliterate them by incision or ligature, as anciently practised, (*Paul. Ægin. Sprengel*, t. vii.,) and in modern times successfully by Delpech, they should be exposed as high as possible. (See *Alf. Velpeau, Anat. Chir.*, p. 199, t. ii. 8vo, Paris, 1838.)

Mr. Mayo joins J. L. Petit, Callisen, and Richerand, in stating that it is more frequent on the left side than the right, "owing to the position of the sigmoid flexure of the colon over the left spermatic veins. For the same reason (he adds) it is often benefited by purging." (*Outlines of Human Pathology*, p. 562.) M. Blandin also specifies, as one cause of varicocele, the pressure of the large intestine on the spermatic veins. (See *Dict. de Med. et de Chir. Prof.*, vol. xv. p. 562.) The circumstances of the spermatic veins having no valves, a long course, and but feeble coats, and the blood in them having to ascend against its own weight in the erect posture of the body, must all give a tendency to a varicose affection of its lower branches. It is sometimes alleged, that even in persons who are not habitually costive, the left spermatic veins are naturally more tortuous and capacious than the right. Cruveilhier also takes into the account the generally larger size and lower situation of the left testicle, as possibly concerned. (*Blandin*, vol. cit., p. 564.) Persons who ride much are very liable to the disease, and so are residents in warm climates.

In general, nothing more is required than the suspensory bandage, cold applications, purgatives, and sometimes leeches, to remove any temporary uneasiness or pain resulting from varicocele; and then the disease remains stationary, the patient merely wearing the suspensory bandage, without which the uneasiness mostly soon returns. Patients with varicocele should also have recourse to cold bathing, and avoid costiveness; which precautions, if not adequate to effect a radical cure, will generally keep the disease from making progress and becoming troublesome.

Gooch and other writers relate cases, in which the pain was so intolerable and incurable, that castration was the only means of relief. Putting castration out of the question, let us briefly inquire what expedients have been tried when the disease is productive of unusually severe pain, and resists ordinary treatment. Some practitioners, on the authority of Celsus, have cut down upon the varicose veins and put a ligature round them. In one instance, Sir Everard Home, like Paul Cumano, at Trieste, performed such an operation in St. George's Hospital. "In this case, venous inflammation took place, attended with so much constitutional disturbance, that the patient nearly died." (*Sir Benjamin Brodie*, in *Lond. Med. Gaz.*, vol. xiii. p. 379.) At the present day, this use of the ligature is abandoned; for if not followed by a dangerous or fatal attack of phlebitis, it would certainly be so by atrophy of the testicle.

J. L. Petit in several instances cut away the clusters of varicous spermatic veins, as is stated, with such success that, in one instance, where the varicocele had been as large as a child's head previously to the operation, the function of the testicle, which had been in a weakened state, was strengthened by this proceeding. More generally, however, atrophy, or sometimes even suppuration of the testis, might be a consequence of the ligature or excision of the veins. It appears that the latter was what happened to the patient operated upon by Delpech, and by whom this distinguished surgeon was assassinated out of revenge. (See *Blandin, Opér.*, vol. cit., p. 568.)

In the hope of avoiding both phlebitis and atrophy of the testicle, M. Davot recommended passing under the vein, through the integuments, a pin, over which a thread was twisted so as to make pressure. With the same view M. Breschet proposed obliterating the vein by pinching it up together with the skin, by means of a pair of compressing forceps. Another practice is that of Dr. Fricke, which consists in passing a seton, of three or four threads, through the bundle of varicous veins. In a case of varicocele of such severity as to require an operation, Mr. Mayo would be disposed to recommend the application of potassa fusa to the plexus of veins, having first exposed them by dividing the skin. (*Outlines of Human Pathology*, p. 562.)

The practice advised by Breschet or Fricke has the recommendation of simplicity and mildness. But I believe the necessity for any operation is very rare. In one case, where the pain was excessive, and supposed to arise from pressure of the varix on some nervous filament, Sir Benjamin Brodie divided the skin, and then cut through the varix with a pair of scissors. "A little bleeding took place, but none of any consequence; pressure for a few minutes stopped it. The wound healed; no inconvenience followed the operation, and the patient was entirely relieved of the pain he suffered previously." (See *Lond. Med. Gaz.*, vol. xiii. p. 379.) In another case of bad varicocele, in a boy, the same gentleman applied a blister over the tumour, and kept it open, and the varicocele and the pain were considerably lessened by it.

"Breschet's plan of pinching the veins, whether of the cord or of the extremities, by forceps constructed for the purpose, has frequently answered, and has not often been followed by the severe and dangerous symptoms of phlebitis. The parts included in the forceps, not excepting even the vein itself, having sloughed, the ulcer heals. M. Sanson has constructed forceps for the same purpose, with blades so broad, that he keeps the sides of the veins in contact for the extent of nearly an inch. It is said to be not absolutely necessary that the vein should be included between the blades of the instrument, nor that adhesive inflammation should arise. It is sufficient that the vein be compressed, so as to stop the course of the blood when a clot forms, which is subsequently absorbed, leading to obliteration of the cavity of the vessel."—(*J. C. Crosse.*)

The passing of needles through the varicous vein, after the ingenious manner first practised by Mr. Benjamin Phillips, for the obliteration of arteries, has been recently tried by Lallemant, Davat, and Velpeau. The last has also passed needles beneath the vein, and twisted a ligature circularly, or in the direction of the fig. 8, under the projecting ends of each needle, so as to compress the vein. Mr. Crosse has likewise tried this plan, and, although there was suppuration in the cellular substance, neither general fever nor phlebitis arose, the patient being quickly cured of a troublesome ulcer, and the dilated vein restored, or obliterated. In University College Hospital, Mr. Liston follows the same practice, with the improvement of withdrawing the pins at the end of about forty-eight hours, whereby the sloughing and ulceration, produced by the pins being left to make their way out, as exemplified in the method adopted by the above mentioned practitioners, are completely avoided. I consider this practice, as modified by Mr. Liston, to be, upon the whole, one of the best and safest plans for the obliteration of the channel of a vein.

Mr. Wormald has lately mentioned some cases in which painful varicoceles were relieved by means of a ring, about an inch in diameter, made of soft silver wire, of a suitable thicknses, padded, and covered with wash leather. "Through this (says he) I drew the lower part of the scrotum, whilst the patient was in the recumbent position, and the veins comparatively empty. I then pressed the sides of the instrument together with sufficient force to prevent the scrotum escaping. The use of this instrument, every morning before the patient rose from his bed, enabled him to walk nineteen miles on the third day after its application; and although he has for six years worn an instrument of this description, he has never experienced the least inconvenience." (*Med. Gaz.*, April, 1838. *J. A. Murray, de Cirsocele*, Upsal, 1784. *Pott on Hydrocele, &c. Richter* in *Nov. Comment. Goett.* No. iv. and in *Obs. Chir.* fasc. ii. p. 22. *Gooch, Chir. Works. Most, Diss. de Cirsocele*, Halæ, 1796.)—C.]

[Dr. J. C. Warren, of Boston, has been eminently successful in the treatment of this disease. In one case, he employed only a temporary ligature; in ten cases, he used pins with the ligature; and in nineteen cases, he performed excision; and in all these cases cured the disease.

Dr. J. Mason Warren, of Boston, has operated on fifteen cases with the same success; in three, he excised the veins; in four, he used the ligature; in six, he employed the pins; and in two cases, he adopted Sir Astley Cooper's plan, by excision from the scrotum.

Dr. Geo. W. Norris, of Philadelphia, reports in the Amer. Journal and Med. Examiner, for 1838, cases of cirsocele and varicose veins, upon which he operated with success, by the method of Davat.

Dr. N. R. Smith has invented a new method of excising a portion of the scrotum, on Sir A. Cooper's plan of treating varicocele, and which has very great advantages. He employs two flat semicircular blocks of wood, perforated near their round edge, for the passage of the needles, and for applying the ligatures; fissures are left upon the edges of the blocks, so that the sutures may be all tied immediately after the excision, and before removing the blocks. His success is the best evidence of the superiority of his mode of operating.

Dr. F. H. Hamilton, of Rochester, has a paper in the Boston Med. and Surg. Jour., for October, 1841, in which he criticises all the various modes of operating for the radical cure of varicocele, and reports two cases, in which he divided the cord, ligated the vessels, and removed the testis on the affected side. In both cases, virility remained as perfect as ever. Dr. H. thinks that castration is, in many cases, preferable to any other mode of operating for varicocele, and that the diseased testis being removed, there is less danger of the loss of virility by the destruction of the other testis, than if the gland of the other side remain and perish, as it does under the other modes of cure.—REESE.]

[VEINS, DISEASES OF. It was not till the latter part of the last century that any other disease of the veins than *varices*, or varicous enlargements of them, received particular attention. At that period John Hunter noticed the fact of the veins in horses being sometimes found to be reddened, thickened, and filled with pus. (*Trans. of a Soc. for the Improvement of Med. Knowledge*, 1793.) The observations which he also made on the local and constitutional effects of the inflammation of the veins in the human subject, drew considerable attention to the disease, on which a great deal of interesting pathological and practical information now exists.

In some points, the diseases of veins resemble those of arteries; but, in others, they differ from them. Thus, as Andral remarks, in the veins no morbid state is observed, corresponding, strictly speaking, to aneurism; because their coats all yield equally to any pressure to which they may be subjected; whereas, in the arteries

it is only the external coat which is capable of yielding in this way. (*Précis d'Anat. Pathol.*, t. ii. p. 392.) The veins are rarely the seat of calcareous concretions, which are very common in the arteries; organized coagulated blood is more frequently met with in the former than the latter; and the same remark is made by M. Andral with respect to pus. "When pus is met with in arteries, (says he,) it must in the majority of cases be looked upon as having had its source in these vessels; but when met with in veins, it may either have been produced in them, or have been introduced by absorption." (P. 93.)

When the inflammation of veins is not very extensive, its symptoms are the same as those of local inflammation in general; but when the inflammation extends into the principal venous trunks, and pus is secreted into the vessel, it is accompanied with a high degree of constitutional irritation, and with symptoms which bear a striking resemblance to those of typhus fever.—(*On the Diseases of Arteries and Veins*, p. 511, 512.)

Inflammation frequently produces a thickening of the coats of the veins, as well as adhesion of their sides and obliteration of their cavities. Indeed, in some instances, these vessels have been found to resemble arteries in the thickness of their coats, and in retaining a circular form when cut across. (*Hodgson, Op.* cit., p. 513.)

Ulceration sometimes extends to the coats of veins, and by exposing their cavities gives rise to hemorrhage. In certain examples, it commences in the membranous lining, and destroys the other coats. In general, however, the adhesive inflammation precedes the ulcerative, and by obliterating the cavities of these vessels, prevents the occurrence of hemorrhage. When sphacelation takes place in the vicinity of veins, their cavities, like those of arteries under similar circumstances, are filled with extensive plugs of coagulum, which prevent hemorrhage upon the separation of the mortified part.

Veins are sometimes ruptured without any previous morbid alteration in their structure, and the accident may be induced by muscular exertions, external violence, the sudden effects of the cold bath, &c.

Although a deposition of calcareous matter almost invariably takes place in the arteries of persons advanced in life, it is an extremely rare occurrence in the coats of veins.

Loose calculi have been found in the cavities of veins; and tumours sometimes grow from their lining. In a case of scirrhous pylorus, Mr. Hodgson found a tumour, larger than a hazel-nut, growing from the lining of the splenic vein, and resembling, in its appearance and consistence, the disease which existed at the pylorus. (P. 524.)

The venous, like the arterial system, appears to be capable of carrying on a collateral circulation, when any part of it is impervious. Even after the obliteration of the vena cava inferior, the blood has been known to be conveyed with facility to the heart through the lumbar veins and vena azygos. In the case recorded by Dr. Baillie, (*Trans. for the Improvement of Med. and Chir. Knowledge*, vol. i. p. 127,) the vena cava was obliterated at the point where the *venæ cavæ hepaticæ* opened into it, so that not only the blood from the lower extremities, but also that from the liver, must have passed through collateral channels to the heart.

To inflammation of veins, M. Breschet first applied the very appropriate name of *phlebitis*, which, as M. Cruveilhier remarks, belongs both to medicine and surgery; there being a *traumatic phlebitis* and a *spontaneous phlebitis*, independent of any previous local injury. In France, he believes he has ascertained, that the greater number of individuals who die in consequence of wounds and surgical operations, perish from phlebitis. (See *Dict. de Méd. et de Chir. Prat.*, t. xii. p. 638, and *Anat. Pathol.*) In this metropolis, we find that a certain proportion of persons so circumstanced are thus destroyed, but not to the same extent as seems from M. Cruveilhier's account to happen at Paris.

Another division of phlebitis, adopted by this eminent pathologist, is, first—into *phlebitis of free veins*; secondly, *phlebitis of veins contained in the substance of organs*; and, thirdly, *capillary phlebitis*. It is also distinguished into *adhesive phlebitis*, where merely fibrine, or coagulable lymph, is effused within the vessel; and *suppurative phlebitis*, where pus is formed; the latter difference being decidedly the most important in relation to the severity and danger of the affection.

The first effect of every phlebitis is the coagulation of the blood, which becomes adherent to the inner coat of the vessel. Such coagulation is observed, both in *traumatic* and in *spontaneous* phlebitis; and it constantly took place in the experiments which Professor Cruveilhier made in living animals, whether by the introduction of a slender stick, or of a stimulating injection into the veins. In consequence of the interruption of the venous circulation in the inflamed vessel, the blood in it becomes stagnant, and, unless the collateral veins suffice for the circulation, there is an effusion of serum in the neighbouring parts. The painful œdema, the *phlegmasia alba dolens*, of puerperal women, as well as that which follows phlebotomy, or under any other circumstances, may be considered, says M. Cruveilhier, as a characteristic mark of phlebitis, and it is generally proportionate to the interruption of the venous circulation of which it is the consequence. But, besides œdema, external phlebitis is accompanied with a hard, painful, and circumscribed cord, which runs precisely in the course of the vein. *Inflammation of the lymphatics* is readily known from phlebitis, by the minute size of the painful cord; its more superficial situation; the numerous small knots, which are perceptible in it; the rose-coloured redness of the skin in the course of such cord; and other particular circumstances depending upon inflammation of the lymphatic vessels. But, with respect to the diagnostic differences, between inflammation of deep-seated veins, and that of deep-seated lymphatics, M. Cruveilhier is of opinion, that they have not yet been determined.

The greater number of examples of phlebitis, even when abandoned to themselves, do no exceed the degree of inflammation which has, for its results, the coagulation of the blood with adhesion of the clot to the vessel, and which M. Cruveilhier terms *adhesive phlebitis*. Now (says he) this adhesive phlebitis is as frequent as solutions of continuity in the veins: there is no childbirth without adhesive phlebitis in the uterine veins, corresponding to the placenta; no amputation, no wound, no ligature of the umbilical cord, without adhesive phlebitis in the divided veins. (*Cruveilhier, Op.* et vol. cit.)

The adhesive form of phlebitis cannot be re-

garded as a very serious disease. The effects which follow the coagulation of the blood, do not extend beyond the affected vein. The blood gradually becomes deprived, first, of the serum which it may contain, and, secondly, of the colouring matter, the remaining fibrine either becoming organized or absorbed, and, in both cases, the veins being rendered impervious. In other instances, as M. Cruveilhier observes, several facts and experiments tend to prove, that a passage for the blood may be formed through the coagulum, so that the vessel that has been the seat of phlebitis may, after a time, be restored to its function in the circulation.

The formation of compact adherent clots, constituting adhesive phlebitis, is described by Cruveilhier as productive of no inconveniences; the individual being even unconscious of its existence, except when it occupies a certain extent, and causes more or less interruption of the circulation in the corresponding parts. Thus, (says he,) adhesive phlebitis of the sinuses of the dura mater is mortal, because the venous circulation of the brain is more or less intercepted. Thus, phlebitis of the femoral or external iliac vein occasions a more or less firm œdematous swelling of the lower extremity, and sometimes even an impossibility of the circulation being carried on by the collateral veins; but (adds M. Cruveilhier) phlebitis is positively curable in this first stage, even in uterine phlebitis. (See *Dict. de Méd. et de Chir. Pratiques*, art. *Phlebite.*)

In many cases of phlebitis, neglected, or treated unsuccessfully, the formation of an adherent coagulum is only the first stage of the disease; suppuration is the second; and the phlebitis, which was at first *adhesive*, now becomes *suppurative*.

It would appear, that certain states of the atmosphere, or of particular localities, in short, all those which promote the occurrence of hospital gangrene and typhus, give a tendency to suppuration in veins; and hence, MM. Ribes, (*Soc. Méd. d'Emulation*, t. viii. 1817,) Breschet, (*Journ. Complém.*, t. ii. and iii. 1819,) and Bouillaud, (*Revue Méd.*, Juin, 1825,) have regarded the symptoms of typhus as more or less directly connected with phlebitis, or the presence of pus in the veins.

According to the investigations of M. Cruveilhier and other pathologists, a frequent cause of the conversion of adhesive phlebitis into the suppurative, is some irritation of parts already in a state of inflammation, as, for instance, that produced either by attempts repeated at short intervals to extract dead bone, or a ball; that resulting from amputation performed in parts, which are the seat of an inflammatory process; or, still more commonly, the plugging up of an inflamed wound for the stoppage of secondary hemorrhage.

With respect to the local changes attending the suppuration of veins, the first is the deposite of pus; and according to M. Cruveilhier, this happens, not between the vein and the clot, but in the very centre of the latter. At first, it has the appearance of wine lees, and then it becomes white and opaque. "The presence of pus (says he) in the centre of clots of blood, has led to the idea, that these clots were directly organized, and capable of inflammation and suppuration; in the same manner as it is admitted that the pus, or serum, which, in pleuritic effusions, is circumscribed on every side by a recently formed false membrane, is the product of an exhalation from this membrane itself; but it seems to me more rational to admit, that the coagulum in phlebitis, and the false membrane in pleurisies, serve, in some measure, as filters, *through which the products pass, which are secreted by the internal membrane of the vein, or by the pleura. The presence of pus, then, in the centre of a coagulum would appear, according to my view, to be a phenomenon of the capillary system.*" (*Cruveilhier, Op.* et vol. cit., p. 641.) I quote this statement, because it presents, in a few words, the opinion of a most distinguished pathologist, on a point which is of some importance in relation to the theory of suppuration. (See SUPPURATION.) There are some examples of suppurative phlebitis, where the disease does not exceed that first stage, in which the pus occupies the centre of the coagulum, and then the purulent deposite is absorbed, and the removal, or the organization of the coagulum itself may next ensue, without the presence of pus having been indicated by any symptom. But, if suppurative phlebitis continues to make progress, the proportion of the coagulum diminishes; that of the pus augments; and the vein soon becomes distended with this fluid. The pus is very seldom remarked to occupy uninterruptedly a considerable extent of the vessel. The inflammation, as M. Cruveilhier observes, not having the same degree of intensity at different points of the course of the vein, the result is that adhesive phlebitis, or incipient suppurative phlebitis, are intercepted by completely suppurative ones, and most commonly an adhesive phlebitis is situated at the limits of the suppuration, so as precisely to circumscribe it. All these appearances are excellently depicted in Cruveilhier's great work. (*Anat. Pathol.*, liv. xi. pl. 1.)

In a more advanced stage, the distended vein becomes knotty at the points where the pus accumulates. Such distention may be carried to the degree, in which one might suppose the case to be an abscess, not situated within the vein. After a time, indeed, the coats of the vein may give way, and then the pus becoming effused around, an abscess really follows suppurative phlebitis, and bursts externally; in which abscess it is sometimes difficult to recognise the vein, a more or less considerable portion of which is destroyed. To this stage of suppurative phlebitis, M. Cruveilhier refers—1. The fact, recorded by Mr. Travers, who found the internal jugular vein perforated, and communicating with a neighbouring abscess. 2. That reported by M. Raikhem, who found the right common iliac vein replaced by a very narrow ligamentous sort of cord, the extremity of which was lost in a large abscess, situated in the cellular tissue of the pelvis, on the right side of the bladder. Nor could the slightest vestige of the femoral vein be detected, its track being occupied down to the ham by a train of circumscribed purulent matter. 3. M. Cruveilhier himself published an instance of suppuration, perforation, and partial destruction of the femoral, popliteal, posterior tibial, peroneal, and other veins, with communications existing between these vessels and abscesses. (See *Nouv. Bibl. Méd.*, 1826, t. ii. p. 179.) "In this case, (says M. Cruveilhier,) I was able to trace all the degrees of phlebitis, from coagulation of the blood to complete destruction of the vessel."

Phlebitis, even in the suppurative forms, produces only local consequences so long as the pus is circumscribed by the adhesive inflamma

tion, and the portion of the vein, which is the seat of suppuration, is excluded from the circulation of the blood. We find this condition described by John Hunter. Professor Cruveilhier adduces the following example of it: a woman, soon after delivery, was attacked with phlebitis in one of the superficial veins of the breast; the vessel formed a large indurated painful cord, extending transversely directly below the nipple: a fluctuation was felt at the inner extremity of this cord. There M. Cruveilhier made a puncture, and was surprised to find that the vein was immediately emptied by pressure made in the direction from without inwards, and the prominence of it converted into a furrow. Suppuration went on for a fortnight, and the pus frequently collected again in the vein, in consequence of the closure of the small opening. The pus was succeeded by a limpid, serous fluid, the constant precursor of consecutive adhesive inflammation, which was soon manifested. However extensive phlebitis may be, provided the pus collected in the vein does not communicate with the mass of circulating blood, the effects of the disease are entirely local. The pus, like that of other abscesses, may be absorbed; or it may distend and thin the vein, and make its appearance through the ulcerated coats of the vessel, so as to cause an abscess liable to be mistaken for a common one. But, as M. Cruveilhier adds, no sooner is the dike formed by the clots broken, and secretly removed by absorption, and the stream of fluid around it, than typhoid symptoms immediately begin, preceded by violent shiverings, and soon followed by death. Frequently, the patient, who had been left perfectly free from indisposition on the previous evening, is found in the morning in a desperate state: in some cases, very nearly the precise moment of the entrance of the pus into the circulation may be specified. (*Cruveilhier, Dict. de Méd. et de Chir.*, t. xii. p. 643.)

Another fact, particularly explained by the same pathologist, is, that no ordinary mark of inflammation is ever noticed upon the inner surface of the vein in the various stages of phlebitis; that is to say, no injection of capillary vessels can be remarked. The deep red colour, noticed by Cruveilhier and other pathologists, resembles a kind of stain, or imbibition. This, it would seem, is observable in the adhesive stage, and entirely vanishes when pus takes the place of the coagula. These facts M. Cruveilhier deems of much importance, because the absence of the anatomical phenomena of inflammation from the internal coat of the veins, and more especially of all injection of the capillaries, has served as the principal argument of writers, who contend that pus found in a vein is not formed there, but in some other point of the system, whence it has been conveyed by means of absorption: but, as he observes, there are some membranes which cannot be injected either in the healthy or morbid state: such are serous membranes; the delicate epidermic pellicle investing mucous membranes; the internal coat of a vein, and also the cellular tissue. When there is no adherent coagulum, and no pus in the vein, it is by the vascularity of the external coat, and the cohesion and brittleness of the cellular tissue on the outside of it, in which a plastic lymph has been deposited, that one may recognise the traces of venous inflammation.

It has sometimes been supposed that the inflammation of a vein always extends only in one direction towards the heart, or in the course which the venous blood itself takes; but this is a mistake as anybody may convince himself by reading the interesting particulars of a case of phlebitis following a gunshot wound of the arm, as recorded by Cruveilhier, (*Anat. Pathol.* livr. xi.,) and the plate representing the appearance of the veins. There it will be seen that phlebitis may extend simultaneously, not only in the direction towards the heart, but in the opposite one, by continuity to the smaller veins.

Professor Cruveilhier has given an excellent description of the general phenomena of phlebitis, which are such as are very usually ascribed to the absorption of pus; namely, exceedingly bad typhoid symptoms, under which the patient sinks with more or less rapidity. "On opening the body, numerous circumscribed collections of purulent matter are found in the lungs, liver, spleen, brain, and muscles; purulent effusions in the synovial and serous membranes; and (what is particularly remarkable) this internal mischief is most frequently unattended with any other local perceptible alterations of the affected organs. For the illustration of this part of the inquiry, M. Cruveilhier adverts to the most common phlebitis, that which is the consequence of wounds and surgical operations. The earliest observers, who endeavoured to detect the cause of death in such cases, did not fail to notice the existence of internal abscesses in the principal viscera, and especially in the liver and lungs. Modern pathologists having become also fully acquainted with the frequency and gravity of these lesions, do not hesitate to regard them as an ordinary cause of death from wounds. Now, as the greater number of the subjects of wounds and surgical operations were known to have been previously in perfect health, the serious mischief in their viscera could not possibly be supposed to have existed prior to their wounds. The question then arises, whence does the purulent matter come from?

The doctrine of the absorption and deposition of pus, says M. Cruveilhier, so long disbelieved, as well as all the other humoral doctrines, has lately been revived, and supported with much talent by M. Velpeau in a series of interesting memoirs, and also by MM. Maréschal and Eugene Legalois. These authors admit that pus, secreted in the deep-seated parts, or on the surface of the body, may be absorbed, circulate with the blood, and be deposited in the substance of this or that organ, without any previous inflammatory process in the seat of such deposite. The facts adduced by these pathologists, M. Cruveilhier acknowledges to be as facts unassailable; but it is their interpretation of them which he conceives may be attacked. "MM. Velpeau, Maréschal, and others, have seen pus in the veins, in the right cavities of the heart, and in the centre of clots of blood. Like them, says M. Cruveilhier, I have seen the same things: all modern observers have likewise done so. Not less frequently also (*Anat. Pathol.*, livr. xii.) I have found pus in the lymphatic vessels. Like them, I have seen collections of pus in different organs; the lungs, the liver, the brain, the spleen, the muscles, and the synovial membranes, without any manifest vestiges of inflammation around. The veins, the lymphatic vessels, and the heart, though they contained pus, seemed also to me devoid of the anatomical characters of inflammation." (Vol. cit., p. 647.) M. Cruveilhier then offers various

reasons, which appear to him to be in favour of the formation of pus in the situations where it is met with. He objects to explanations, in which the metaphorical expression, *sympathy*, is substituted for fact. "If the liver is so often affected in wounds of the head, it is, according to Desault and Bichat, because the liver and gastric organs are so closely connected with the brain by sympathy. The whimsical and opposite modes of accounting for abscesses of the liver after injuries of the head, adopted by Pouteau and Bertrandi, are well known. M. Richerand suggested the notion that these abscesses were owing to the simultaneous contusion, or concussion of the liver and the brain; and this view may afford a satisfactory explanation of some hepatic abscesses; but the production of those abscesses, with which are to be arranged inflammations of the synovial and serous membranes, muscles, and cellular tissue, is too general a fact, and, in the majority of instances, too independent of all concussion and contusion, to permit the adoption of so limited an explanation."

Anatomy is invoked in vain to lift the veil that hides these phenomena. The porosity of our textures, which, according to the ancients, allowed fluids to filter from one place to another, as through a sponge; the perviousness and continuity of the cellular tissue, in the cavities of which Bordeu made so many fluids, and even so many causes of disease, move about; imbibition, endosmosis and exosmosis, substituted of late for the porosity of the ancients; the continuity of the nervous and vascular systems; the sympathetic correspondences; the law of *consensus*; in a word, the whole science of organization, are all confessedly incapable of accounting for so extraordinary an occurrence. An inflammation, which seemed to have nothing to do with that now under consideration, phlebitis, has filled up the great void, that seemed to separate the suppurating wound from a visceral abscess. A series of numerous experiments which I published in 1826, (*Nouv. Bibl. Méd.*, t. iv.,) appear to me to have rigorously established this proposition: *Every foreign body introduced in the living subject into the venous system, occasions, when its discharge by the emunctories is impossible, visceral abscesses, completely resembling those consequent to wounds and surgical operations; and such abscesses are the result of capillary phlebitis in these same viscera.*

"If any irritating fluid, such as ink, for example, is thrown into the femoral vein of a dog, (in the direction from the heart,) which is practicable after a few of the valves have been destroyed with a probe, and the collateral veins do not convey the liquid into the circulation, in which case the injection proves immediately fatal, the limb in 36 hours becomes swollen, and if the animal then dies, or is killed, innumerable bloody extravasations are found in the substance of the muscles, and in the cellular tissue of the limb. The large veins are distended with coagulated and adherent blood; and the small veins, corresponding to the extravasations, are also full of concrete blood, while those appertaining to the healthy parts are free. If the animal survive the experiment, collections of pus replace those of blood, at the same time that pus is substituted for the coagulated blood in the veins." M. Cruveilhier, instead of using a chemical irritating means, next employed a mechanical one; he pushed a stick into the femoral vein of a dog, from below upwards, into the ascending vena cava. The dog died on the sixth day. The lower extremity was anasarcous, the infiltration extending up to the parietes of the chest. All the veins of the lower extremity were full of pus. When the muscles were divided, small abscesses were seen here and there in them, which proved to be minute veins, swollen with purulent matter, which could easily be pressed out of these vessels." Amongst other effects noticed by Cruveilhier, there was also a collection of pus in the synovial membrane of the knee.

M. Cruveilhier then endeavoured to ascertain what became of the pus of a local phlebitis, when such pus was mixed with the mass of circulating blood; but, since purulent matter cannot be detected when blended with the blood, he was obliged to employ in lieu of it mercury, a liquid, the smallest particles of which, however situated, would admit of being traced. Now, he found, that if mercury be introduced into the venous system, whatever be the way of its entrance, (excepting through the abdominal system,) the mercury is always found again in the lungs. Thus, (says M. Cruveilhier,) if a large quantity of quicksilver be injected into the jugular or femoral vein, the animal will become exceedingly oppressed, and perish, in twelve, eighteen, or twenty-four hours, in a state very analogous to that observed in asthma, or suffocative catarrh. The whole of the mercury will be found again in the lungs, which will not be inflamed, but gorged with serosity, that may be compressed out of them. But if the quantity of quicksilver is smaller, the animal will survive the experiment a longer time, and then there will be perceived an induration around each globule of the mercury; in a later stage, collections of pus, and, at a still more advanced period, a mixture of pus and tubercular matter. Lastly, if the animal survive for two or three months, tubercles are found with a globule of quicksilver in the centre of each of them.

M. Cruveilhier submits to the contemplation of physiologists the following experiment, which he has varied in a thousand ways, and always with the same result. He destroyed the medullary texture of the femur, and substituted quicksilver for it. The dogs experimented upon lived four or five days, and, on opening them, he found all the quicksilver scattered through the lungs, and each globule encompassed by a degree of inflammation. The quicksilver was lodged in the ramifications of the pulmonary artery, which we know perform in the lungs the office of veins.

The liver being the seat of a particular system of veins, which are destitute of valves, and have numerous ramifications in the mesentery, M. Cruveilhier drew out a knuckle of intestine, and injected quicksilver into one of the mesenteric veins. In a dog which survived this operation twenty-four hours, he found the liver studded with red, superficial, and slightly prominent patches, of the colour of wine lees; and its texture when cut into on a level with these patches, presented the same colour to the depth of four or five lines. In the centre of each small red induration was a globule of quicksilver; a certain quantity of which had penetrated into the small veins which ramify on the coats of the intestines. Opposite these small intestinal veins, the mucous membrane was of a bright red colour, and lined with a false membrane and bloody mucus. The corresponding subperitoneal cellular tissue, and the muscular coat itself, were also of a crimson hue.

In another experiment on a dog, which had an umbilical epiplocele, M. Cruveilhier injected quicksilver into a small vein of the omentum. In about ten weeks the animal was destroyed. The omentum was found adherent to the cicatrix of the abdomen; and, through its whole extent, a great many semi-transparent, very firm tubercles, scattered or agglomerated. The liver was studded with innumerable yellowish tubercles, some of which lay near its surface; others in its substance, and each having in its centre one or more globules of quicksilver. Some of them presented two distinct strata; one of a tubercular substance at the circumference, the other of puriform matter in the centre, in the middle of which were the mercurial globules. The preceding facts seem to M. Cruveilhier to prove that all extraneous bodies, introduced into the general circulation, are inevitably conveyed to the lungs, and such as enter the abdominal venous system, as certainly proceed to the liver; these viscera constituting a barrier, which they cannot pass beyond except in certain cases.

The experiments quoted by M. Cruveilhier solve one difficulty, which clinical observation alone could never have solved: how, in the hypothesis concerning phlebitis, is the pus conveyed from the general venous system into the capillary system of the liver? Should not the pus stop in the capillary vessels of the lungs? It seems as if abscesses should only take place in the latter organs; yet experience proves, that abscesses of the liver are very common after wounds and surgical operations, and this, notwithstanding the capillary system of the liver only communicates directly with the vena portæ and the hepatic veins. But this objection is at once reduced to its proper value by the demonstration of that subtile liquid, quicksilver, passing completely through the capillary system of the liver, when injected into the branches of the vena portæ; and, in other cases, passing through the general and pulmonary capillary systems; or, what is still more convincing, pervading several times the different orders of capillary vessels.

Professor Cruveilhier, therefore, considers it to be proved, with all the exactness of physical experiments, that pus, introduced into the circulation with the blood, is stopped in different departments of the capillary system; that it everywhere excites capillary phlebitis, or circumscribed inflammations, which advance more or less rapidly to the state of abscesses; that pus, like quicksilver, is most frequently stopped in the lungs, and next in the liver and spleen; and that, like quicksilver, it may pervade the capillary system several times in succession, and occasion circumscribed inflammations in all parts of the body.

The next questions which M. Cruveilhier considers are, why do not multiplied visceral abscesses take place in cases of copious accumulations of pus, for instance, in those from chronic pleurisy and peritonitis? Is it necessary that there should be a traumatic phlebitis in some part of the system to produce a capillary phlebitis in the viscera? All observers, and Quesnay in particular, he says, have noticed the vast difference in relation to consecutive effects between abscesses of long standing, and the suppuration from recent wounds. To what is this difference ascribable? Is there absorption of pus in one instance, and not in the other? The following is the explanation immediately derived from the facts:—Whenever a fluid, capable of being imbibed, is in contact with a suppurating surface, whether such fluid be secreted by the textures of the body, or be extraneous to the economy, it is absorbed. The absorption of pus is continually taking place. "I will not cite (continues M. Cruveilhier) the numerous facts, which prove the occasional presence of pus in the lymphatic vessels and glands, because pus, so situated, might be regarded as the product of their inflammation; but I will cite the very sudden and repeatedly observed disappearance of large abscesses, the opening of which has been deferred." Yet, the constitution undergoes no disturbance from this cause, and the heterogeneous matter is eliminated by the emunctories. It appears to M. Cruveilhier, that there is immense difference between pus which is transmitted into the circulation by absorption, and pus which is directly introduced into it, without having undergone any modification, or preparation, by the act of absorption, or which is produced immediately within the veins themselves. (See *Anat. Pathol. Phlebité Utérine*, liv. iv.; *Inflammation des Sinus de la Duré Mère*, liv. vii.) "Pathological as well as physiological absorption does not act upon substances in a mass, but successively on their different elements, which are thereby modified. Pus, in particular, would appear to be in the first instance deprived of its most fluid part; its solid part is not absorbed till a later period, and frequently not till it has acquired a caseous consistence; but pus, in its natural condition, directly blended with the blood, alters its crasis, (as the ancients would say,) embarrasses its course, promotes its coagulation, stops it in the capillary vessels, and, at the same time, gives rise to inflammation at numerous points." (*Cruveilhier, Dict. de Méd. et de Chir. Pratique*, t. xii. p. 657.)

It may be objected that, if the foregoing theory were true, multiplied abscesses in the viscera ought always to be preceded by phlebitis in some part or another; yet, frequently, they are met with, and no traumatic suppuration can anywhere be detected. It is to no purpose that all the veins are inspected, not only those which adjoin a wound, but others remote from it; nowhere can any marks of phlebitis be traced. Now, on this fact, which excited Mr. Arnott's notice, M. Cruveilhier argues that, unless the state of the medullary canal, or spongy texture of the bones, be examined in such cases, the inference is of no value, because incomplete. M. Dance seems to have been the first pathologist who gave a correct explanation of the cause of abscesses of the liver from wounds of the head, viz., the inflammation of the deep veins, not merely of those which ramify in the brain and its membranes, but also of those which penetrate the bones of the cranium—the veins of the diploe. Pus formed in the diploe, or the meningeal veins, may reach the liver as well as the lungs, and, indeed, every part of the venous capillary system; for the liver is not exclusively affected in wounds of the head, and, as M. Cruveilhier remarks, if many observers have only specified the liver, it is because they were mostly satisfied with the inspection of that viscus. "What M. Dance proposed as a conjecture, has been completely established. In several cases of wounds of the head, the veins of the diploe have been found purulent, and this state coexisting with abscesses of the liver and lungs.

Several convincing specimens of this were presented to the Anatomical Society; and, at the present time, it may be announced (says M. Cruveilhier) as a demonstrated truth, that, in cases of wounds of the head, the visceral abscesses, whether of the liver, the lungs, or spleen, &c., are the consequence of phlebitis, and more especially of phlebitis of the diploe; but the observation, that inflammation of the veins of bones, as a cause of visceral abscesses, applies, not only to the veins of the diploe, but to all the veins of bones; and I lay it down as a general proposition, that *phlebitis of bones is one of the most frequent causes of visceral abscesses, after wounds and surgical operations implicating the bones.*" (*Op.* et. vol. cit., p. 660.)

Traumatic phlebitis comprehends—1. Phlebitis from venesection. 2. From the division, excision, or ligature of veins in the treatment of varices: plans, which Cruveilhier is surprised are not the subject of universal reprobation, considering the fatal consequences frequently occasioned by them. 3. Phlebitis from wounds of the head, gunshot wounds, compound fractures, various surgical operations, lithotomy, the extirpation of ulcerated polypi, the excision of hemorrhoids, the prolonged continuance of a catheter in the bladder, &c. Phlebitis has been known to follow incisions for the extraction of balls, the removal of fatty tumours, a meliceris of the head, and even a mere contusion of the leg. (*Cruveilhier.*) The last case of phlebitis which I met with, arose from a severe contusion of the elbow, where abscesses formed, communicating with the joint, attended with severe constitutional disturbance, and soon followed by abscesses in both legs, and pus in the synovial membranes of the ankle joints. No suppuration could be traced in the lungs or liver; but the medullary texture of the bones of the arm was not examined. Phlebitis may indeed come on in the suppurative stages of many diseases. I have known it arise as a consequence of an enormous carbuncle, and lead to the formation of numerous abscesses, several of which occurred in different synovial cavities.

Uterine phlebitis is known to be one of the worst forms of puerperal fever. Next to traumatic phlebitis, one of the most frequent cases is phlebitis of the lower extremities, consequent to uterine and hypogastric phlebitis. This form of it, however, may take place under two distinct conditions: 1. After parturition. 2. In cases of cancer of the womb. But, for information on these topics, I must refer to the writings of Dr. D. Davis, Dr. Robert Lee, Professor Cruveilhier, (*Anat. Pathol.*, liv. xxvii.,) and others.

With regard to the treatment of phlebitis, this must vary according as the affection happens to be in the adhesive or the suppurative stage. Or rather, I might say with Professor Cruveilhier, the only period when any means are likely to avail, is that very early one of the coagulation of the blood within the vessel; for when suppuration has taken place, and pus has actually entered the circulation, medicine is generally ineffectual. Just as an external phlebitis is daily seen to be checked by bleeding, cold applications, the free administration of calomel, and the application of numerous leeches in the course of the inflamed vein, so may internal phlebites, whatever be their situation, be stopped by early recourse to copious bleeding, and to the free use of leeches and mercury. I believe all the best practical writers on uterine phlebitis give their testimony in favour of rigorous antiphlogistic treatment, adopted in the earliest stage of the case. Dr. Robert Lee is an advocate for it, and Professor Cruveilhier, in his practice at the *Hôpital de la Maternité*, believes, that he has often subdued uterine phlebitis by means of general and local bleeding; resorted to early, and practised with freedom; but, as he observes, no sooner is the first stage over, and the constitutional derangement begins, than bleeding and leeches have no beneficial effect. Doubtless, he remarks, this may take away, with the blood, a portion of the material cause of the disease, but such cause continues to be incessantly reproduced, and the patient, together with his blood, is deprived of the power of reaction. Under these circumstances, bark, sulphate of quinine, carbonate of ammonia, ether, wine, brandy, and opium, or the preparations of morphia may be tried, with or without two or three grains of calomel every night, and with repeated blisters and warm applications. However, it is attested by all who have seen much of suppurative phlebitis, attended with the effects resulting from the direct entrance of pus into the circulation, that no treatment, hitherto suggested, appears to possess any great power over this form of the disease.—C.]

[*Ligature of the Internal Jugular Vein.*—The following operation is original with Professor Stevens, and has not before been published.

"The question of the possibility of tying the internal jugular vein in operations for the extirpation of tumours in the neck is one to which the attention of surgeons must have often been directed with great anxiety. The records of our art do not furnish, to my knowledge, any case in which this operation has been attempted. That which I am about to relate establishes the important fact that it may be tied with safety.

"A man of middle age came under my care in the New York Hospital during the last winter, (1830,) with an extensive flattened tumour under the sterno-mastoid muscle, formed of the chain of lymphatic glands which accompanies the great vessels on the left side of the neck, in a state of great enlargement. It had been the subject of a previous unsuccessful operation, and was then alarmingly obstructing the powers of deglutition and respiration. In the course of my operation for the removal of this tumour, after it had been detached, except at its inner and posterior edge, I drew the tumour outwards and forwards, and divided a vein of considerable size, passing horizontally outwards, near its junction with the internal jugular. Half an ounce of venous blood escaped, and in an instant afterward a peculiar sound was heard, like that occasioned by drawing into a syringe the last portions of water from a basin. It was a moment of intense anxiety, for the fate of Dupuytren's patient was fresh in my recollection. I immediately placed my finger on the aperture in the vessel, seized the pulse with the other hand, and watched the patient's countenance. All seemed well, and the patient's reply to my interrogatory confirmed these favourable indications. After a moment's deliberation, I determined to pass a ligature around the internal jugular, below and above the junction of the wounded branch. It was accordingly separated from the par vagum and carotid with the blunt point of an eyed probe, armed with a double ligature; one of which was secured below and the other above the wounded vessel. The operation, of which

little remained to be done, was then completed. The man suffered from cough and difficult respiration between the fourth and seventh days after the operation, for which he was twice bled and took saline purgatives. The ligatures came away on the fourteenth day, and the case went on without any peculiarities.

"If the par vagum can be divided on one side without endangering life, a question, I believe, not yet settled by positive experiment, the proposition will be established, that many tumours in the side of the neck (the removal of which is now deemed impracticable) may be successfully extirpated."

The internal jugular vein has been twice tied successfully by Dr. J. C. Warren, of Boston.

Professor Hamilton, of Geneva College, who was unfortunate enough to cut the internal jugular vein, in an operation upon the neck, thrust a sponge into the wound, and allowed it to remain until suppuration removed it. The frightful hemorrhage was thus stayed, and the patient recovered.

In the Amer. Journ., for 1836, Professor Sewall, of Washington, publishes a letter from a medical friend in Paris, narrating a case of death, in the Hôtel Dieu, from the entrance of air into the veins, in the operation of amputation at the shoulder joint, performed by the celebrated Roux. This letter communicates the opinions of Magendie on the subject, together with experiments performed on living animals, in confirmation of his views. To this brief, but valuable article, I have only space to refer the reader.—Reese.]

[VEINS, VARICOSE. Modern pathologists make a distinction between veins affected with simple *hypertrophy*, and veins in the *varicose state*. "Hypertrophy of veins (says Cruveilhier) is observed in all cases, where a great normal or morbid nutritive action takes place in an organ; as exemplified in the uterine veins during pregnancy, and in cases of considerable fibrous or medullary tumours, or other growths in the substance of that viscus." Another cause of hypertrophy is some impediment to the course of the blood in the veins, &c. Whatever may be the cause, venous hypertrophy is characterized, not only by dilatation of the veins, but by an increase of their length, so that those which are rectilinear become at first tortuous, and afterwards curiously twisted on themselves, attaining at last four or ten times their natural length, and not recognisable, &c. When the dilatation occurs uniformly at every point of the circumference of the vessel, the blood circulates freely, *there is no varix;* but, if one point of the circumference undergo a change of structure, it yields, and then the blood is detained in it; and a small spherical thin pouch is formed. In this the blood coagulates, adheres to its interior, loses its red colour, and in the centre of the pale fibrine, calcareous concretions are produced. Sometimes the coats of the varicose cyst inflame, burst, and give rise to hemorrhages, always easily stopped, but which may prove fatal. There is then this great difference between dilatation and varix; that, in one there is integrity of the venous coats, in the other, an alteration of them; in one, the vein fulfils all its functions in relation to the circulation; while, in the other, there is a stagnation of the blood and disease." (*Cruveilhier, Anat. Pathol.*, liv. xvi.) Certain facts, however, noticed in this article, prove that the kind of distinction specified by Cruveilhier is not always applicable, inasmuch as the blood is not invariably stagnant in varicose veins, and calcareous formations are only occasionly met with in them. M. Andral identifies not less than six varieties of varix:

1. Simple dilatation of veins without any other change, such dilatation affecting either their whole length, or occurring at intervals. 2. Dilatation, either uniform, or at intervals, with a thinned state of the vein at the dilated points. 3. Uniform dilatation, with thickening of the venous coats. 4. Dilatations at intervals, with thickening of the dilated points. In these two last, at the same time that the vein increases in diameter, it increases also in length, and becomes bent and tortuous. 5. Dilatation, with the addition of septa within the vein, whereby the cavity is divided into little cells, in which the blood lodges and coagulates. 6. A similar disposition, combined with perforations in the parietes of the vein, which communicates with the surrounding cellular tissue in a more or less diseased state, by numerous small apertures. "In dissecting a great number of true hemorrhoidal swellings, (says M. Andral,) never will any thing else be detected, but one or the other of these six varieties of phlebectasiæ, (varices;) but this is not merely the case with veins about the verge of the anus. I once met with the disposition, constituting the sixth variety, in the external jugular vein." (See *Andral, Précis D'Anat. Pathol.*, t. ii. p. 400.)

Professor Cruveilhier has recorded the particulars of a man in whom there was an enormous dilatation of the subcutaneous abdominal veins, which freely communicated with the vena portæ, through the intervention of the umbilical vein, the size of which was equal to what it usually presents in the fœtus. (See *Anat. Pathol.*, liv. xvi. pl. 6.) The disease rarely occurs before the adult period of life, and its progress is extremely slow. It is very frequently remarked in pregnant women, who have passed a certain age; but it is particularly unusual for it to happen in young women, even during a series of repeated pregnancies. Surgeons have not hitherto made out any very precise information respecting the kinds of constitution which promote the occurrence of a varicose enlargement of the veins. Nor has it been well proved that the disease often proceeds from swellings of the abdominal viscera, or any other species of tumour capable of mechanically obstructing the venous circulation. One or more veins of the same limb are at first most commonly affected with a slight degree of dilatation, without pain or any sensation of uneasiness. This beginning change ordinarily advances with great slowness, except in cases where it accompanies pregnancy, in which circumstance, one or both the lower extremities, as early as the first months, are frequently seen covered with largely dilated veins, or even with tumours formed by an assemblage of varices. The veins gradually become more and more distended, lengthened, coiled up, and tortuous. The patient then begins to complain of a sense of heaviness, numbness, and sometimes of very acute wandering pain through the whole of the affected limb. In a more advanced age, in proportion as the varices increase, and especially when the dilated veins actually form tumours, the limb swells and becomes more or less œdematous, according to the extent of the disease, and the time which it has existed. Delpech

thinks, however, that the œdema in this case is not such as to justify the conclusion, that the increased size of the veins, and the way in which they distend the integuments, produce a mechanical interruption of the function of the absorbent system. For, says he, enormous varices are sometimes, though not often met with, which are not attended with any swelling of the cellular substance; and cases are still more frequently seen in which there is a considerable degree of œdema, while the varices are scarcely remarkable. When the latter have prevailed a long while, and made much progress, the coats of the affected veins are not unfrequently thickened, swelled, and indurated, forming a sort of half canal or solid tube. As Mr. Hodgson remarks, "the blood occasionally deposites strings of coagulum in varicose veins; when this is the case, the vessel is incapable of being emptied by pressure, and is firm to the touch. The deposition does not in general fill the vessel, but by diminishing its calibre, it retards the flow of blood, and causes the dilatation to increase in the inferior portion of the vein, and in the branches which open into it." (*On Dis. of Arteries and Veins*, p. 541.) This gentleman has seen four cases, in which the coagulum accumulated to such an extent, that the canals of the dilated vessels were obliterated, and a spontaneous cure was the consequence. The excessive distention of the coats of a superficial vein produces an inflammatory irritation, at first in the adjoining cellular membrane, and afterwards in the integuments. These textures become at first connected together by the adhesive inflammation; and if the distention continue to operate, they may at length ulcerate, and burst, and hemorrhage be the consequence. In such cases, the effusion of blood is sometimes considerable; but the syncope following it or a moderate compression, generally suffices for its stoppage.

M. Velpeau cites one case, in which the bleeding from a varix of the leg proved fatal; and I have heard of other similar occurrences. In varix of the extremities, accompanied by chronic ulceration of the integuments, as Dr. Carswell observes, extensive hemorrhage may be the result of perforation of a vein, not larger than a common quill. "I had (says he) an opportunity of examining the vein in an example of this kind, the morbid condition of which, and of the surrounding cellular tissue, afforded a satisfactory explanation of the fatal extent of the hemorrhage. The walls of the vein were much thicker than those of an artery of the same size, and were so firmly united with indurated cellular tissue, that a considerable degree of pressure was required to approximate their internal surface. The consequence of this condition of the vein was, that its capacity would undergo no diminution during the hemorrhage, the blood continuing to escape, as through an inanimate tube, by the opening which had been effected by ulceration. This patient, who was about 40 years of age, expired in the space of little more than ten minutes." (See *Carswell's Illustrations of the Elementary Forms of Disease; Fasc. on Hemorrhage.*)

By tying the principal venous trunk above the point to which the varicose branches proceed, it was believed that the flow of blood through them might be so retarded and impeded, that they would afterwards become filled with concrete blood, and then gradually subside. The operation of tying the venous trunk with two ligatures, and cutting through the vessel in the interval, has been accurately described by some of the old writers.

After the account of the perils of suppurative phlebitis, as already given in this article, it is unnecessary for me to offer any further comment on the unjustifiable nature of this operation. In England it is now universally abandoned.

Mr. Ferrall has published an interesting paper, in which he notices the occasional suppuration of the wound after this operation. Such an event took place in some of Mr. Carmichael's cases, notwithstanding every precaution. Between the years 1824 and 1829, Mr. Ferrall performed the operation four times. In three of these suppuration occurred; this he imputes to a degree of laceration of the cellular tissue in turning the knife, proposed by Sir Benjamin Brodie, which was also sometimes found to bend. On this account, Mr. Ferrall recommends another knife with a straight back, and made as thin as possible for about a quarter of an inch from its point, without forming there a cutting edge. Previous to the operation, Mr. Ferrall surrounds the limb with straps of soap plaster, nearly as high as the situation of the cluster of varicose veins, and a roller is applied in the same course, ready to be continued up the limb, when the division is complete. The object of this is to lessen the flow of blood through the tortuous vessels, and consequently their distention and irritation below the point of incision, when the current is interrupted. Mr. Ferrall deems it advantageous to let the bleeding go on for a little while. After the operation, a compress is laid on the part, and the roller, wetted with an evaporating lotion, continued up the limb. The patient is then put in bed, with his limb on a pillow, and the heel higher than the knee. For additional details I refer to Mr. Ferrall's paper. (See *Dublin Journ. of Med. Science*, vol. ii. p. 230—234.)

Even when the vein was divided, and the skin left untouched, Béclard saw sometimes phlebitis, and sometimes phlegmonous erysipelas, produced by the operation. (*Malgaigne, Man. de Méd. Opér.*, p. 164, ed. 2.)

A few months ago, however, Sir Benjamin Brodie informed me, that he now rarely or never adopts the plan, as he believes that much of the relief which he formerly imputed to the operation, is the effect of quietude in the recumbent position observed after its performance.

The actual and potential cautery are ancient means for the cure of varices. Of late years, Mr. Mayo has in a considerable number of cases applied caustic, or caustic paste, over the trunks of the subcutaneous veins of the leg affected with varix. In some few instances, on the healing of the ulcer left by the separation of the eschar, no effect on the vein was observable; but, in much the greater proportion, the vein became firm and hard, and its cavity was obliterated at the part where the issue had been made. "I have little doubt, (says he,) that in the successful cases, the irritation upon the vein has caused local subacute inflammation, as a consequence of which the blood has coagulated in its cavity, and plugged it. The vein is often tender during several days, for the extent of three or four inches above the place at which the caustic is applied. The obstructed part does not exceed more than half an inch to an inch in length. I have never known acute phlebitis supervene in employing this practice. In one case, occurring

in a young woman, an inexperienced dresser made a circular eschar, two inches in circumference, and deep in proportion, over the saphenic vein immediately below the knee; it opened the saphena, and within six hours there was violent venous hemorrhage; this, of course, stopped on pressure being applied. During the next few days, there was tenderness of the saphena, extending half the length of the thigh, over which leeches were applied once." The case ended well. (See *Mayo's Outlines of Human Pathology*, p. 433.)

Instead of dividing the skin, and tying or cutting through the trunks of varicose veins, or the excision of clusters of them, or the obliteration of them with caustic, another practice has arisen, viz., that of raising up the vein, together with the skin covering it, and then passing under the vessel a long needle or pin. The vein being elevated by means of the pin, is pressed down upon it, and then firmly constricted with thread twisted round the two projecting portions of the pin in the manner of the twisted suture. The subjacent pin, and the thread over the vein, press and flatten it; stop the flow of blood through it, and produce local inflammation in it, which is at first adhesive, then ulcerative, and terminates in the obliteration of the cavity, and the division of the venous coats. In about eight or twelve days the pin is withrawn, the threads removed, and the slough formed in the seat of the compression, left to separate of itself. The remaining sore soon heals up. This method, which was first tried on animals by M. Davat, has been practised by M. Velpeau on twenty-five patients for varices, and with almost constant success. (See *Malgaigne, Man. de Méd. Opér.*, p. 161. *Dict. de Méd. et de Chir. Prat.*, t. xv. p. 545.) It appears never to have been followed by any of the bad consequences too frequently occasioned by the simple ligature of the vein. In the treatment of varicose veins, M. Sanson adopted M. Breschet's plan for the relief of varicocele, (see this word;) while Dr. Fricke has, in not less than thirty instances, extended the use of the seton to the cure of varices, as well as varicocele, and with successful results. M. Velpeau tried the method twice; transfixing the vein from before backward, and then bringing out the needle again from behind, as Dr. Fricke recommends; but, as a good deal of phlegmonous inflammation followed, M. Velpeau thinks that if this plan be selected, the needle should be passed only in one direction in making the seton, as in Dr. Fricke's operation for the cure of varicocele. (See *Malgaigne, Op.* cit., p. 163.)

The application of tincture of iodine to the skin covering varicose veins has been suggested. I have seen it tried in University College Hospital, but without any benefit, except what might be ascribed to quietude in the recumbent position, adopted in conjunction with it.

In surgical operations, when large veins are divided, *air may enter them*; and, if in considerable quantity, the patient is suddenly destroyed. I believe that the first instance in which such a catastrophe was particularly noticed and accounted for, took place in the practice of Dupuytren. The experiments made by M. Poiseuille led him to infer, that air can only insinuate itself into such veins as are unprovided with valves, (*Journ. Hebd. de Méd. et de Chir.*, 1831:) but wounds of veins, in so many different situations, have sometimes been followed by this occurrence, that the foregoing inference is not admissible; nor, as the air takes the course of the blood, is it likely that the presence of valves would make such a difference. Thus, patients are stated to have been suddenly destroyed, or brought into most imminent danger, from the rush of air into veins, in operations performed by Dupuytren and Beauchêne, about the neck and shoulder, (*Piedagnel, Thèse.*, Paris, 1827; and *Archiv. Gén. de Méd.*, t. v. p. 424;) on the thyroid gland, by Graefe, (*Journ. de Physiol. Exp. de Magendie*, 1829;) on the shoulder, by Castara, (*H. Saucerotte, Thèse.*, Strasburg, Mars, 1829;) and Delpech, (*Mém. des Hôpitaux du Midi, 2de Année*, p. 654;) on the breast and axilla, by Dr. Warren, (*Gaz. Méd. de Paris*, Mars, 1833;) Sir Astley Cooper and M. Goulard, (*Thèse.*, Paris, 1834;) above the clavicle, by M. Roux, (*Journ. Hebdom.*, t. xi. p. 165;) in the armpit and on the chest, by M. Clemot, (*Lancette Franç.*, 1831;) and on the face, by Dr. Mott, (*Amer. Jour. of the Med. Sciences*, Nov. 1828.) (See *Alf. Velpeau, Anat. Chir.*, t. i. p. 105, 8vo, Paris, 1838.)

Some of the cases here referred to, however, I think, will not be generally acknowleged as clear and unequivocal examples of death or urgent peril from the entrance of air into the veins, though others seem to admit of no question. These seem to me to leave no doubt of this being the occasional cause of death; but did any ambiguity exist upon the subject, it would be dispelled by the experiments instituted on animals in relation to this point, by MM. Magendie and Piedagnel.

The greater number of examples of death or imminent peril from the admission of air into the veins, have certainly occurred in operations about the neck. Hence, even in opening the external jugular vein, Baron Larrey's advice, not to discontinue the pressure on that vessel below the opening, until a compress has been applied, is well deserving of being attended to; for otherwise a slight operation might be converted into a suddenly fatal wound. (See *Alf. Velpeau, Anat. Chir.*, t. i. p. 491.)

The particulars of a similar disastrous accident, which happened in the practice of M. Roux, may be read in a modern work. (See *Dubl. Journ. of Med. Science*, vol. iv. p. 475.) The patient in this case revived, however, and lived seven days afterwards. (See other cases detailed by Dr. Warren, in *Amer. Cyclop. of Pract. Med. and Surgery*, ed. by Dr. Hays.) In one of these, the temporal artery was opened, and the patient, after being insensible for two hours, recovered. In another, where the air had entered a vein divided in the axilla, the patient, a woman, aged 33, was lost, notwithstanding the use of external and internal stimulants, and even laryngotomy, as a last resource.—C.]

[Dr. J. C. Warren has operated upon thirty-nine cases of varicose saphena, and has variously employed the ligature, pins, and the division of the vein, adapting the method to the cases. So far as heard from, he has had uniform and permanent success.

Dr. Joseph Parish having witnessed several deaths in the Pennsylvania Hospital, from tying veins for the cure of varicose affections, coincided with Sir Astley Cooper, in reprobating this practice.

Dr. J. Watson, surgeon to the New York Hospital, applies a tourniquet to the limb, above the enlarged vessels, and then making an incision at several points, especially where the

veins anastomose, from the lower part of the thigh downwards, even as far as the foot, exposing the enlarged vein at the bottom of each incision, but without wounding the vessel, until all the incisions have been made from above downward. He then removes a small portion of each vein exposed, proceeding from below upward, and applies pressure, so as to avoid hemorrhage. At each point he removes from half an inch to an inch of the enlarged vessel, thus completely intercepting the course of the blood. After thus excising the veins, the integuments are drawn together with adhesive straps, and a circular roller applied. The following day, if there be no contra-indication, by great uneasiness in the limb, the roller is passed over, and the limb dressed as with the starch bandage. The patient is kept in the horizontal posture for a fortnight, and the bandage remains undisturbed all this time. The limb being then exposed, the wounds are usually found to be completely united by adhesion, and the varicose vessels obliterated. In two cases, Dr. Watson has thus operated on both the external and internal saphena at the same time, and no difficulty has attended the return of the blood by the deep veins of the leg. The patients treated by this method, thus far, have had no return of the disease, and some of them have been cured nearly a year. In many cases of varicose veins, Dr. Watson's plan will be found to possess great advantages over any other, and the operation is certainly creditable to his skill and science. It is certainly less dangerous, less tedious, and if successful in effecting a radical cure, of which his experience thus far is in evidence, it must soon supersede the ligature, the pins, the seton, or the caustic.

Dr. Mutter has frequently performed Ricord's operation for varicose veins, by subcutaneous ligature, and with gratifying results. He expresses himself greatly pleased with this method.

Dr. Parker, of New York, was the first surgeon in America who practised the subcutaneous ligation of varicose veins, which he did successfully in 1831. He has also treated cirsocele in the same way, and with the like success.

Dr. Armsby, of Albany, has adopted a modification of Sir B. Brodie's operation, by the subcutaneous division of varicose veins, and with entire success. He applies a firm bandage to the limb, over its whole length, and continues it for weeks afterwards, with a graduated compress over the wound.—Reese.]

W.

[WRY-NECK. As early as the year 1759, a case of wry-neck and distortion of the jaw, caused by contraction of the platysma myoides, was cured by division of that muscle. (See Dieffenbach, in Lancet, for Sept., 1838.)

M. Guèrin, of Paris, has devoted great attention to this interesting subject, and Dr. John Mason Warren, of Boston, has published a paper on the subject, in the Boston Med. and Surg. Journ., for Sept. 29, 1841, abounding with valuable matter, both of a critical and practical character. He avails himself of the exposition published by M. Guèrin, on the pathology, physiology, and surgical treatment of wry-neck. Dr. Warren has operated twice with the most gratifying success, and upon formidable cases, requiring the division both of the sternal and clavicular portion of the sterno-cleido-mastoideus muscle, and in one, dividing the body of the muscle, just above its division, into its sternal and clavicular heads. In this case he was able to detach the muscle between the thumb and forefinger, and isolate it completely from the deep-seated parts; and he pursued the plan of Guèrin, by cutting from within outward, on the subcutaneous method. In the other case, Dr. Warren employed a narrow, sharp-pointed bistoury, and cut from without inward, still, however, making but one orifice, and dividing the sternal-mastoid, and then the cleido-mastoid, near their attachment, subcutaneously. His complete success is creditable to his science and skill.

In the reports of these cases, which are very carefully made, we find a confirmation of the anatomical changes and general deformities with which wry-neck is so frequently complicated, and all dependant upon the contraction of this muscle. The whole osseous system, as well as the soft parts, is found to be involved. There is an inclination of the cervical vertebræ on the dorsal, of the dorsal on the lumbar, and of the lumbar on the sacral. The whole spinal column participating, there is an excavation of the ribs on one side, and a projection on the other. The face and head, especially on the side of the contracted muscle, are found to be atrophied, and an oblique position is communicated to the side of the face by the traction of the skin, resulting from the distortion. The eyeball also undergoes a rotation on its axis, so as to bring it into the horizontal direction, which occasions both a deformity and an obstruction to the vision for a time, after the restoration of the head to its normal position.

The morbid affections of the head and face are ascribed by M. Guèrin to the distortion which the great vessels of the neck undergo, before their entrance into the cranium. He also lays down the following propositions on the general subject:—

1st. The sterno-cleido-mastoid muscle constitutes, in fact, two distinct muscles—the sterno-mastoid and the cleido-mastoid.

2d. These two muscles are possessed of different functions, the sterno-mastoid being a flexor and rotator of the head, while the cleido-mastoid is essentially a muscle of respiration.

3d. In wry-neck the sternal muscle is primitively affected.

4th. In the treatment of chronic wry-neck, owing to the shortening of the sterno-mastoid, the section of the sternal portion alone suffices to destroy the essential cause of the deformity.

M. Guèrin regards acute cases as curable by the local application of antimonial ointment and other medication, depending as it does simply on muscular *contraction*; but in chronic cases, he thinks a *retraction* of the muscle by reason of a fibrous degeneration, requires surgical interference. It is only in these latter that myotomy is necessary, and their long persistence

may render the division of both portions of the muscle necessary, as in the two cases reported by Dr. Warren, while in a majority of examples the sternal portion only will require to be divided; suitable mechanical means being subsequently employed, by bandaging and otherwise, such as will occur to any intelligent surgeon. Dr. Warren found in his cases, that to place the patient on an inclined plane for three or four hours daily, with the head secured by a bandage carried under the chin, and attached to the upper part of the board, was a valuable auxiliary. He recommends the narrow blunt-headed knife of Bouvier as preferable for this operation.

The following cautions of Dr. Warren indicate the dangers of this operation, and will enable the surgeon to avoid them:—

In dividing the internal head of the muscle, we have occasionally beneath the skin the anterior jugular vein as it passes across the neck, to enter the subclavian. This, however, is easily avoided by making the incision sufficiently near the clavicle. The carotid and internal jugular are protected by the sterno-hyoid and sterno-thyroid muscles, and could not be reached but by the point of the knife carelessly introduced. In dividing the cleido-mastoid, the external jugular, which lies between the border of the muscle and the skin, may be wounded; this is avoided by raising the skin, and passing the knife with its cutting edge perpendicularly to the muscle, the vein being left between the back of the instrument and the skin. In dividing the body of the muscle, the external jugular is the principal organ to be avoided, and with sufficient care may be easily left on the outside of the puncture necessary for introducing the knife employed in the operation.

The old operation for wry-neck, by making a transverse incision through the skin, exposing the fibres of the muscle, and then dissecting it layer by layer, ought never to be repeated, now that the comparative superiority of the subcutaneous incision has been so amply demonstrated. The inflammation and suppuration consequent upon the old method were severe and dangerous, sometimes fatal, from the purulent infiltration into the anterior mediastinum. So also the contraction of the cicatrix, after so severe a wound, often defeated the operation. Indeed, in many other operations, but especially in this, the principle of subcutaneous incision is to be regarded as one of the most important improvements of modern surgery. Its establishment is doubtless due to Stromeyer, who was led to its adoption in his earliest operations on club-foot, by his anxiety to avoid the difficulties and dangers which Delpech had encountered in his memorable case. This is the secret of Stromeyer's success, for in other respects he availed himself of Delpech's principles and practice as his guides.

Dr. Nathan R. Smith, of Baltimore, has operated successfully by myotomy for this disease several times since 1828, the date of his first case, and in his last two cases he has adopted the subcutaneous method, with manifest advantage over the former mode of operation.

Dr. Mott, of New York, has successfully divided the sterno-cleido-mastoid muscle five times for torticollis. He prefers the old method by cutting through the integuments, and dividing the muscle from without inwards, with suitable caution, and then healing the wound by granulation, dressing it with lint. He saw M. Guèrin repeatedly perform the subcutaneous section of this muscle in Paris, and witnessed its repetition again and again on the same patient, which was rendered necessary by the muscle reuniting when thus divided, a difficulty which is incidental to this plan, but against which the old method gives immunity. Besides, the subcutaneous section is necessarily hazardous, because of the proximity of the sheath containing the large vessels; and though M. Guèrin cuts from without inward, and even from within outward, subcutaneously, and avoids the dangers alluded to, yet there are few beside himself who can do so with safety to the patient. The propriety of a subcutaneous incision, in immediate proximity to large vessels and nerves, when the eye of the surgeon cannot take cognizance of the wound inflicted by his knife, is very questionable. And moreover, the frequent failure to divide all the fibres of the muscle at a single operation, the difficulty of preventing them from uniting, and the necessity of repeating the hazards of the subcutaneous section again and again, are all valid objections against this method. Indeed, in myotomy, the same reasons for avoiding a wound of the integuments do not exist as in tenotomy.

Dr. Mott has lately treated a case of wry-neck dependant on paralysis of the sterno-mastoid on one side, so that by the action of the antagonist muscle the distortion was perpetual, and had existed over a year, during which the lady had been treated unsuccessfully, both by local and general means. The paralyzed muscle was soft and perfectly inactive. The healthy muscle on the sound side being divided, the head was at once restored to its normal position, and the distortion has been permanently removed.—REESE.]

* The editor regrets to say, that several communications, from eminent American surgeons, have been necessarily omitted, as they failed to reach him in time.

THE END.
